**CKD, chronic kidney disease; ESA, erythropoetin-stimulating agent; HD, hemodialysis; PD, peritoneal dialysis.**

*aSmall dosage ranges (e.g., 25–150 mg per week) generally used for maintenance regimens. Larger doses (e.g., 1 g) should be administered in divided doses.

# Supply

*aSupplied in 2-mL single-dose vials containing 50 mg of elemental iron per mL.*

*aAvailable in colorless glass ampules containing 62.5 mg elemental iron (12.5 mg/mL).*

*aSupplied in 5-mL single-dose vials containing 100 mg elemental iron (20 mg/mL).*

*aSupplied as a 17-mL single-use vial containing 510 mg elemental iron (30 mg/mL).*
allergies may be at increased risk of anaphylactic-type reactions.\textsuperscript{62,63} The potential for increased risk of reactions with concomitant use of angiotensin-converting enzyme inhibitors and iron dextran is also highlighted in the labeling for iron dextran, and a statement is included to clarify that there are differences in the chemical characteristics and clinical effects of available iron dextran products (e.g., Dexferrum and INFeD) since these agents are often erroneously considered interchangeable.\textsuperscript{63}

The risk of adverse events with iron dextran was particularly influential in product selection prior to the availability of sodium ferric gluconate, iron sucrose, and ferumoxytol. These IV iron formulations have a better safety record than either of the iron dextran products, based on their history of use in Europe over the last 4 decades (sodium ferric gluconate and iron sucrose) and data in the United States since these products were approved.\textsuperscript{65,66} These newer agents do not require administration of a test dose prior to administration of the full dose. As a precaution with all IV preparations, patients should be observed during and immediately following administration for any adverse reactions.

Administration of IV iron also introduces a risk of iron overload. Deposition of excess iron may affect several organ systems, leading to hepatic, pancreatic, and cardiac dysfunction. Bone marrow biopsy provides the most definitive diagnosis of iron overload, but because it is an extremely invasive procedure, it is not widely employed in most clinical settings. Maintaining serum ferritin and TSat values that demonstrate efficacy in preventing iron deficiency yet are safe is the most reasonable approach to minimize the risk of iron toxicity. The challenge is in defining these upper limits, particularly for serum ferritin, which may be elevated in inflammatory conditions and not reflective of true iron stores in such situations. If symptomatic overload does occur, deferoxamine (Desferal) or phlebotomy may be necessary.

**Dosage Considerations.** The safety and efficacy of high-dose IV iron regimens have been evaluated to determine the most cost-effective and efficacious dosing strategies. Iron dextran has been safely administered to dialysis patients in total-dose infusions ranging from 400 mg to 2 g.\textsuperscript{65} Similar high-dose regimens of 500 mg have also been safely administered to patients with stage 3 or 4 CKD.\textsuperscript{66} Sodium ferric gluconate has been safely administered at doses of 250 mg infused over 1 hour (4.2 mg/min).\textsuperscript{67} In this same evaluation, 19 doses greater than 250 mg were administered; 1 dose of 312.5 mg, 14 doses of 375 mg, and 4 doses of 500 mg, with infusion rates varying from 1.22 mg/min to 25 mg/min. No serious adverse events were reported, although nonserious events, such as pruritus, did occur in 4 of the 144 patients who received the 250 mg dose. If doses higher than those currently approved are used in practice, they should be administered over a prolonged time period (e.g., at least 2–3 hours). Iron sucrose at doses of up to 500 mg administered over 3 hours on consecutive days has been successful in maintaining iron stores without causing serious adverse events.\textsuperscript{68}

When administered over a shorter time period this same dose was associated with dizziness, hypotension, and nausea.\textsuperscript{69} In this same evaluation the administration of lower doses of 200 to 300 mg given over 2 hours resulted in fewer adverse events. Higher-dose regimens for iron sucrose have been approved in patients with early-stage CKD and peritoneal dialysis patients (see Table 53–7), populations in whom administration of higher doses are more convenient as these patients are seen less frequently by healthcare providers than the hemodialysis population.\textsuperscript{58} Ferumoxytol was approved in 2009 for use in the adult CKD population, including dialysis and nondialysis patients. The approved dose is 510 mg administered at a rate of up to 30 mg per second, a higher dose and administration rate compared with other available IV iron formulations.\textsuperscript{70,71}

Although there are conflicting reports, most clinicians believe that exposure to iron may contribute to the risk of bacterial infection because iron is used by microorganisms for metabolic functions. The association of IV iron with oxidative stress, acceleration of atherosclerosis, and other cardiovascular conditions has also been suggested.\textsuperscript{72,73} These potential long-term risks of IV iron therapy are not clearly defined, and there are no data confirming unequivocally that aggressive use of IV iron in CKD patients treated with ESA therapy increases patient morbidity or mortality.

As a superparamagnetic oxide, ferumoxytol may affect the diagnostic ability of magnetic resonance imaging studies; therefore, these imaging studies should be done prior to administration of ferumoxytol when possible. These effects may persist for up to 3 months following administration of ferumoxytol. Ferumoxytol will not interfere with x-ray, computed tomography, positron emission tomography, single photon emission computed tomography, ultrasonography, or nuclear medicine imaging.\textsuperscript{66}

**Erythropoietic-Stimulating Agent Therapy.** Erythropoietic-stimulating agents (ESAs) are glycoproteins manufactured by recombinant DNA technology that have the same biologic activity as endogenous erythropoietin. Available ESAs in the United States include epoetin alfa (distributed as Epogen by Amgen, Inc., Thousand Oaks, CA; and Procrit by Ortho Biotech, Johnson & Johnson, Raritan, NJ) and darbepoetin alfa (Aranesp by Amgen, Inc., Thousand Oaks, CA). Epoetin beta is available from several sources outside the United States (e.g., NeoRecormon, F. Hoffmann-La Roche).

Since 1989, epoetin alfa has been the mainstay of therapy for anemia of CKD. Darbepoetin alfa was approved for treatment of anemia of CKD in September 2001. Darbepoetin alfa differs from epoetin alfa by the addition of two N-linked carbohydrate side chains, which increases the molecular weight (~37 kDa for darbepoetin compared with 30.4 kDa for epoetin alfa). The increase in sialic acid content decreases the affinity of darbepoetin for the erythropoietin receptor, but extends the half-life compared with epoetin alfa.\textsuperscript{74}

**Pharmacokinetics and Pharmacodynamics.** Epoetin alfa may be administered by either the IV or the subcutaneous (SC) route. Although bioavailability with SC administration is approximately 30% to 36% that of IV, the prolonged absorption phase leads to an extended half-life of 24 hours with SC administration compared to 8.5 hours with IV administration.\textsuperscript{75,76} The prolonged half-life with SC administration leads to a more sustained physiologic stimulation of erythroid precursors. Trials have shown that the same target Hb can be achieved and maintained at SC epoetin doses 15 to 30% lower than IV doses.\textsuperscript{75} Darbepoetin alfa has a longer half-life than does epoetin alfa (25.3 hours and 48.8 hours after IV and SC administration, respectively).\textsuperscript{76} More recent information based on studies with prolonged sampling times compared with the original pharmacokinetic studies have reported an even longer half-life of darbepoetin of 70 to 105 hours with SC administration.\textsuperscript{77} The prolonged half-life of darbepoetin offers the advantage of less-frequent dosing, starting at once a week or once every other week when given IV or SC. This is of particular benefit in stage 4 and 5 CKD patients who are not yet receiving dialysis and those receiving peritoneal dialysis. Prolonged dosing intervals, as infrequent as once every 4 weeks, have also been effective in maintaining target Hb in many CKD patients, including nondialysis CKD and ESRD patients.\textsuperscript{77,80}

The pharmacodynamics of epoetin and darbepoetin are important to consider when evaluating response to therapy. With initiation of ESA therapy or a change in dose, the Hb may begin to rise as the result of demargination of reticulocytes; however, it takes approximately 10 days before erythrocyte progenitor cells mature
and are released into the circulation. The Hb continues to increase until the life span of the cells stimulated by epoetin or darbepoetin is reached (mean 2 months; range 1 to 4 months in patients with ESRD). At this point a new steady state is achieved (i.e., the rate at which red blood cells are being produced equals the rate at which they are leaving the circulation). For this reason it is important to evaluate the Hb response over several weeks as opposed to making changes in the dosing regimen prematurely.

**Efficacy.** Patients will generally respond to ESA therapy in a dose-related fashion unless there are confounding factors present that may cause resistance to therapy or failure to respond as defined by the K/DOQI guidelines. The most common causes of resistance are iron deficiency, acute illness, catheter insertion, hypalbuminemia, elevated C-reactive protein, chronic bleeding, aluminum toxicity, malnutrition, hyperparathyroidism, cancer and chemotherapy, AIDS, inflammation, and infection. Erythropoietic therapy may be continued in the infected or postoperative patient, even though increased doses are often required to maintain or slow the rate of decline in Hb. Deficiencies in folate and vitamin B12 should also be considered as potential causes of resistance to ESA therapy, as both are essential for optimal erythropoiesis.

Medicare has developed new clinical performance measures (CPMs) for ESRD providers that emphasize both an upper and a lower limit of Hb. Of note the limits advocated in the new CPMs are based on FDA labeling (Hb 10–12 g/dL [100–120 g/L; 6.21–7.45 mmol/L]) as opposed to the K/DOQI guidelines (Hb 11–12 g/dL [110–120 g/L; 6.83–7.45 mmol/L]).

**Adverse Effects.** Hypertension is the most common adverse event reported with epoetin alfa and darbepoetin alfa and may be associated with the rate of rise in Hb. Protocols established in some clinical settings, primarily in outpatient dialysis clinics, sometimes recommend withholding ESA therapy if blood pressure is above a defined threshold. K/DOQI guidelines for anemia do not recommend withholding ESA therapy for elevated blood pressure, but instead advocate more judicious use of antihypertensive agents and dialysis to control blood pressure; however, according to FDA-approved product labeling ESAs should not be used in those with uncontrolled blood pressure. Seizures have occurred in patients treated with epoetin, particularly within the first 90 days of starting therapy. Vascular access thrombosis may also be more frequent during ESA therapy. The potential for these adverse effects calls for close monitoring of the rate of rise in Hb, changes in blood pressure, and monitoring neurologic symptoms following initiation of therapy or a change in ESA dose.

Data demonstrating a higher risk of adverse outcomes in CKD patients treated more aggressively to Hb targets above 12 g/dL (120 g/L; 7.45 mmol/L) with ESAs prompted the FDA to issue a warning in March 2007 about safety concerns of higher Hb targets. Manufacturers revised the ESA product labeling to include updated warnings, a new boxed warning, and modifications to the dosing instructions. The new boxed warning advises healthcare providers to monitor Hb and to adjust the ESA dose to maintain the lowest hemoglobin level needed to avoid blood transfusions. Of note the Hb target in the product labeling for ESAs is 10 to 12 g/dL (100–120 g/L; 6.21–7.45 mmol/L). An FDA-approved medication guide describing the risks of ESA use must also be given to patients receiving ESA therapy.

Neutralizing antibodies to ESAs have been identified in a relatively small number of patients treated with ESAs; approximately 200 cases were reported between 1998 and 2004. These patients develop antibody-mediated pure red cell aplasia (PRCA), which results in an absolute resistance to ESA therapy and reliance on blood transfusions as the primary therapeutic option. Cases were mostly reported between 1998 and 2002 and occurred in parallel with the increase in SC administration, primarily with one epoetin alfa product manufactured outside the United States, Eprex (Johnson & Johnson, Manati, Puerto Rico). Differences in this formulation that were noted at the time of the increase in PRCA cases were the substitution of human albumin with polysorbate 80 and use of uncoated rubber stoppers in the single-dose syringes, factors that in combination may have increased the immunogenicity of SC-administered epoetin alfa. Changes in packaging of these syringes led to a decrease in PRCA case reports. Although the case reports of antibody-associated PRCA are relatively few in number, further evaluation for PRCA should be considered for patients receiving ESA therapy who develop a rapid decrease in Hb level (rate of 0.5–1.0 g/dL/week [5–10 g/L/week; 0.31–0.62 mmol/L/week]), become transfusion dependent, and have an absolute reticulocyte count of less than 10,000/µL (10 × 10⁹/L) with a normal platelet and white blood cell count. Discontinuation of ESA therapy is recommended in antibody-mediated PRCA because antibodies are cross-reactive and continued exposure may lead to anaphylactic reactions. Immunosuppressive therapy has been effective in up to 50% of patients with PRCA. A peptide-based erythropoietin receptor agonist, hematide, an investigational agent that has a different amino acid sequence than native or recombinant erythropoietin, has been shown to stimulate erythropoiesis in patients with PRCA or hypersensitivity due to antierythropoietin antibodies and may provide another option in the future for individuals with PRCA.

**Drug–Drug Interactions.** No significant drug interactions have been reported with the available ESAs.

**Dosing and Administration.** Recommended starting doses of epoetin alfa are 50 to 100 Units/kg IV or SC three times per week for hemodialysis patients. Less frequent dosing is preferred for stage 4 CKD patients and peritoneal dialysis patients since these patients are seen in the outpatient clinic setting on a relatively infrequent basis. Improved erythropoiesis and reduced transfusion requirements were observed in patients with anemia (Hb <10 g/dL [<100 g/L; <621 mmol/L]) who received once-weekly SC doses of 10,000 Units of epoetin alfa. Monthly dosing intervals for epoetin alfa SC have also been effective in maintaining target Hb values in this population.

The starting dose of darbepoetin alfa in patients not previously receiving ESA therapy is 0.45 mcg/kg IV or SC administered once weekly. A conversion table for patients who are to be switched from epoetin alfa (Units per week) to darbepoetin alfa (micrograms per week) is available in the package insert for darbepoetin. The usual dosing frequency of darbepoetin is weekly for patients previously receiving epoetin two to three times per week and every other week for patients receiving epoetin once weekly. Extended dosing intervals of darbepoetin as infrequent as every 4 weeks have been successful in maintaining Hb levels.

The IV route of administration is preferred for most hemodialysis patients. Subcutaneous administration of ESAs is preferable for peritoneal dialysis patients and the nondialysis CKD population because these patients do not usually have regular IV access. Dose adjustments should be made based on Hb response with consideration of the recent data on risks associated with higher Hb levels and rate of rise in Hb. A general recommendation is to reduce the ESA dose by 25% if the Hb is approaching 12 g/dL (120 g/L; 7.45 mmol/L) or if the Hb increases by more than 1 g/dL (10 g/L; 0.62 mmol/L) in any 2-week period. A 25% increase in dose may be considered if the Hb is below target range and has not increased by 1 g/dL (10 g/L; 0.62 mmol/L) after 4 weeks of ESA treatment and if no causes of resistance to the ESA have been identified. Figures 53–3 and 53–4 provide an algorithmic approach to management of anemia using ESAs and iron therapy in patients with ESRD.

**Transfusions and Adjunct Therapies.** Red blood cell transfusions are currently a third-line treatment option for anemia of
CKD. Red blood cell transfusions carry many risks and therefore should only be used in select situations, such as acute management of symptomatic anemia, following significant acute blood loss, and prior to surgical procedures that carry a high risk of blood loss, with the goal of preventing inadequate tissue oxygenation or cardiac failure. 1-Carnitine supplementation and vitamin C were previously suggested as adjunctive treatments of anemia associated with kidney disease but are not recommended in the K/DOQI guidelines because of the lack of evidence supporting improved anemia management with these therapies.

Pharmacoeconomic Considerations

Pharmacoeconomic considerations in the management of anemia of CKD relate primarily to the costs associated with ESAs and IV iron to sustain erythropoiesis. In the outpatient dialysis environment there is a fee-for-service reimbursement system that was implemented by the federal government through the Medicare system. As a general practice, dialysis facilities are reimbursed for ESAs and IV iron at a rate based on the success of maintaining Hb within specific targets, which have changed as guidelines and clinical performance measures for anemia management have been updated. This fee-for-service reimbursement system led to an increase in average ESA doses; the Medicare cost of ESAs was $1.8 billion in 2007. USRDS data indicate that these costs have stabilized. This is due, in part, to changes in the composite rate administered to dialysis facilities, limits on reimbursement for ESAs if Hb levels exceed upper limits, and the recent warnings about ESA safety, which have led to a decrease in ESA use and target Hb levels.

The results of CHOIR, CREATE, and the NHCT prompted CMS to develop a plan for bundling ESAs along with other separately billable drugs into a single payment system to provide an incentive for dialysis facilities to use ESAs more sparingly and reduce costs. This “bundling” of payments for dialysis services is designed to reduce financial incentives for utilization of ESAs and other previously separately billable drugs. Included in the bundled payment are services provided for the dialysis procedure itself that were included in the previous composite rate, separately billable injectable drugs administered during the dialysis procedure (such as ESAs, vitamin D analogs, iron, antibiotics) and their oral equivalents, and separately billable laboratory tests related to the treatment of ESRD. The proposed payment plan for this bundling system was released in the fall of 2009 and is currently in draft form. Once finalized this bundling system is planned for implementation in January 2011.

Evaluation of Therapeutic Outcomes

Iron status should be assessed every month during initial ESA treatment, and every 3 months for those receiving a stable ESA regimen or for those hemodialysis patients not treated with an ESA. For all ESAs, the initial dose and subsequent adjustments should be determined by the patient’s Hb level relative to the target Hb level, and the most recent observed rate of increase in Hb. Hemoglobin should be monitored at least monthly in patients receiving ESA therapy, although more frequent monitoring (e.g., every 1–2 weeks) is warranted after initiation of an ESA or following a dose change until the Hb is stable. The response to ESA therapy should be evaluated at least over 2 to 4 weeks before a change in the dose of epoetin alfa or darbepoetin alfa is made. New FDA and CMS recommendations now advise healthcare providers to withhold ESA therapy if the Hb is >12 g/dL (>120 g/L; >7.45 mmol/L); some clinicians, however, may institute a dosage reduction of ≥25% to prevent drastic shifts in Hb levels. An algorithm for anemia management is depicted in Figures 53–3 and 53–4.

CKD-MINERAL AND BONE DISORDER (CKD-MBD) AND RENAL OSTEODYSTROPHY

Desired Outcome

The overall goal for management of CKD-MBD is to “normalize” the biochemical parameters and prevent the detrimental consequences, including renal osteodystrophy, cardiovascular and extravascular calcifications, and the associated morbidity and mortality. Unfortunately prospective trials to evaluate the effect of controlling CKD-MBD on these outcomes are limited. At present the K/DOQI (U.S. guidelines) and KDIGO (international guidelines) can be used to guide clinical decision making; however, there are notable differences in these guidelines.

CLINICAL CONTROVERSY

K/DOQI clinical practice guidelines for bone metabolism and disease in CKD have been available in the United States since 2003. Targets for calcium, phosphorus, calcium-phosphorus product, and PTH are defined based on opinion and evidence, when available, and have led to development of standardized protocols. In 2009 KDIGO international guidelines for CKD-MBD were published. Given the lack of randomized, controlled trials to support specific target levels for calcium, phosphorus, and PTH the recommendations for target levels and treatment approaches are much more general. Healthcare providers are left to use clinical judgment and new information as it becomes available to sort out the discrepancies in these guidelines where they exist.

The K/DOQI recommended targets for calcium, phosphorus, Ca × P product, and PTH based on the stage of CKD are shown in Table 53–4. The calcium should be corrected for albumin level. The recommended corrected serum calcium for patients with stage 3 or 4 CKD is within the normal range, whereas the proposed range for patients with stage 5 CKD is slightly lower than the normal range. This lower range for calcium in stage 5 CKD patients is based on observations of an increased risk of soft tissue and vascular calcifications in this population, particularly in those individuals with an elevated Ca × P product. Serum phosphorus concentrations should be within the normal range, with higher concentrations acceptable in stage 5 CKD, in part, because of the challenges of lowering phosphorus. The proposed Ca × P product of 55 mg²/dL² (4.4 mmol/L²) is much lower than the previous recommendation of 65 to 70 mg²/dL² (5.2 to 5.7 mmol/L²). The PTH values recommended for patients with stage 4 or 5 CKD are above the normal range to prevent oversuppression of PTH and reduce the risk of adynamic bone disease. Serum aluminum levels should also be maintained below 20 μg/L (0.74 μmol/L) to minimize the risk of developing aluminum toxicity, a contributing factor to bone disease.

Based on a lack of randomized, controlled trials showing improved outcomes with control of calcium, phosphorus, and PTH within narrowly defined ranges, KDIGO does not define specific targets for these parameters. KDIGO recommends maintaining serum phosphorus within the normal range for stage 3 to 5 CKD patients and lowering phosphorus toward the normal range for dialysis patients. They propose that calcium should be maintained within the normal range for all CKD patients. KDIGO also supports evaluation of trends in calcium and phosphorus values individually as opposed to attempting to achieve a target Ca × P product. Overall,
these recommendations for calcium and phosphorus do not differ drastically from K/DOQI. Clinicians do need to consider risk of calcifications in the stage 5 CKD population and whether a lower target calcium is warranted in individual patients. No specific PTH target range is advocated by KDIGO, but rather the recommendation is to evaluate trends and consider intervention in individuals with values above the upper range for the assay method used. In the dialysis population a broad range for PTH of two to nine times the upper normal limit of the assay is suggested.

Management of PTH, phosphorus, and calcium balance is important in preventing CKD-MBD, ROD, and cardiovascular and extravascular calcifications. Patients with ESRD usually require a combination of dietary intervention, phosphate-binding medications, vitamin D, and calcimimetic therapy to achieve these goals.

Nonpharmacologic Therapy

*Dietary Phosphorus Restriction* Dietary phosphorus restriction should be a first-line intervention for management of hyperphosphatemia in patients with CKD and should be initiated for most patients with stage 3, 4, or 5 CKD. The K/DOQI guidelines recommend phosphorus restriction to 800 to 1,000 mg/day when the upper levels of serum phosphorus are reached (see Table 53–4). This recommendation also applies to patients with PTH levels above the recommended range given the evidence that lowering phosphorus ingestion directly decreases PTH synthesis and secretion. The challenge with dietary restriction of phosphorus is providing enough protein to prevent malnutrition, a common problem in the ESRD population because foods high in phosphorus are generally high in protein. Examples of foods or beverages that contain high amounts of phosphorus include meats, dairy products, dried beans, nuts, colas, peanut butter, and beer. Nutritional goals must be evaluated on an individual basis, preferably by a dietitian specializing in the care of CKD patients. Dialysis patients require a higher protein intake (1.2–1.3 g/kg per day), making restriction of phosphorus even more challenging. Removal of phosphorus does occur with peritoneal dialysis and hemodialysis (approximately 2–3 g/vk, dependent on the dialysis prescription); however, intermittent dialysis alone does not usually control hyperphosphatemia.

One of the most common obstacles to the success of dietary phosphorus restriction is patient noncompliance because of the poor palatability and inconvenience. Regular counseling by a dietitian is necessary to design a realistic diet that works with the patient’s lifestyle.

*Dialysis* Hemodialysis and peritoneal dialysis lower serum phosphorus and calcium, the extent to which is dependent on the concentration of both entities in the dialysate and the duration of dialysis. K/DOQI recommends the dialysate calcium concentration in hemodialysis or peritoneal dialysis should be 2.5 mEq/L (1.25 mmol/L). KDIGO suggests a dialysate calcium concentration of 2.5 to 3.0 mEq/L (1.25–1.50 mmol/L). Dialysis alone cannot control these parameters, and dietary and pharmacologic interventions are also required in the majority of dialysis-dependent ESRD patients.

*Parathyroidectomy* Parathyroidectomy is a therapeutic option for patients with severe CKD-MBD who do not respond to pharmacologic therapy. The K/DOQI guidelines recommend surgery for those patients with persistently elevated PTH (PTH >800 pg/mL (>800 ng/L)) associated with hypercalcemia and/or hyperphosphatemia that are refractory to medical therapy. Surgical approaches include either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of parathyroid tissue to an accessible site, such as the forearm. Postoperative hypercalcemia, hypophosphatemia, and hypomagnesemia may occur because of a marked increase in bone production in relation to bone absorption (“hungry bone syndrome”). Following surgery frequent monitoring of calcium and phosphorus is necessary as described in Chapter 59. Treatment with supplemental calcium and vitamin D may be required for weeks or months.

Pharmacologic Therapy

**Phosphate-Binding Agents**

*Pharmacology and Mechanism of Action.* Drugs that bind dietary phosphorous in the GI tract form insoluble phosphate compounds that are excreted in feces, thus reducing phosphorus absorption and serum phosphorus concentrations. A variety of phosphate-binding agents are available, including elemental calcium-, lanthanum-, aluminum-, and magnesium-containing compounds, and the nonelemental agent sevelamer carbonate (Table 53–8). Patients must be instructed to take these agents with meals to maximize the binding of phosphorus in the GI tract.

*Efficacy.* Oral calcium compounds are well established as first-line agents for control of both serum phosphorus and calcium concentrations, at least in the early stages of CKD when hypercalcemia is more common. Calcium carbonate and calcium acetate are the primary preparations used; calcium citrate is also available but is not recommended since the citrate component increases aluminum absorption. The chloride salt is also not recommended because it is very astringent and unpalatable, and absorbed chloride may contribute to systemic acidosis. Calcium carbonate is marketed in a variety of dosage forms (see Table 53–8) and is relatively inexpensive. Unfortunately, many calcium carbonate products are considered food supplements and thus are not required by law to meet United States Pharmacopeia (USP) disintegration and dissolution requirements. In general, nationally advertised brands meet USP quality standards for disintegration and dissolution, but it is difficult to determine whether private label or house brands conform to these standards. Variability in gastric pH may also affect disintegration or dissolution, and thus phosphate-binding efficacy. Calcium carbonate is more soluble in an acidic medium and therefore should be administered prior to meals when stomach acidity is highest. In addition, acid-suppressing agents such as ranitidine and proton pump inhibitors may reduce the phosphate-binding activity of calcium carbonate by increasing gastric pH. Calcium acetate binds approximately twice as much phosphorus as calcium carbonate at comparable doses of elemental calcium. Increased binding potency limits GI calcium absorption; however, calcium acetate is more soluble, and therefore better absorbed than calcium carbonate in an alkaline pH, which may explain the similar incidence of hypercalcemia with these agents. For patients with hypercalcemia, calcium carbonate or calcium acetate may also be given as a calcium supplement taken between meals to promote calcium absorption.

Although calcium-containing phosphate-binding agents continue to be used as first-line therapy, their chronic use may increase the risk for vascular and tissue calcification. The K/DOQI guidelines recommend that the total dose of elemental calcium provided by calcium-containing binders not exceed 1,500 mg per day and the total daily intake of elemental calcium from all sources not exceed 2,000 mg. Calcium-containing binders are not recommended for dialysis patients who have persistent elevations in serum calcium >10.2 mg/dL (>2.55 mmol/L) or PTH values <150 pg/mL (150 ng/L). KDIGO guidelines suggest restricting the dose of calcium-containing binders in stage 3 to 5 CKD patients if hypercalcemia is present or if arterial calcification or adynamic bone disease (low bone turnover disease) is evident. Since both of these recommendations regarding calcium intake are based primarily on opinion, clinicians in essence have to rely on their past experiences and clinical judgment as they individualize therapy for their patients.
Sevelamer is a nonabsorbable, nonelemental hydrogel phosphate-binding agent. The hydrochloride salt of sevelamer was approved by the FDA in 2000; however, its use was associated with the development of acidosis in some CKD patients. The manufacturer therefore developed the carbonate formulation that provides an added buffering capacity and does not contribute to acidosis. 80 This formulation is available as a tablet and powder for oral suspension and will eventually replace sevelamer hydrochloride. Sevelamer effectively lowers phosphorus and has also been shown to significantly lower LDL and increase HDL cholesterol. 81,82 Whether sevelamer lowers the risk of calcification compared with calcium-containing binders is an issue of some debate. There are studies to support use of sevelamer over calcium-containing binders to decrease progression of arterial calcification in both dialysis and nondialysis CKD patients. 83 These findings have been refuted by other studies showing that sevelamer is associated with similar rates of vascular calcification compared with calcium acetate. 84 K/DOQI guidelines suggest using a noncalcium-containing binder in dialysis patients with severe vascular or soft tissue calcifications, although these are opinion-based recommendations. 21 KDIGO states that binder choice be made considering the stage of CKD, other factors of CKD-MBD such as risk of calcifications, and other therapies. 85

Lanthanum carbonate is a phosphate binder approved for patients with ESRD. Short-term (6–28 weeks) and long-term (2–3 years) therapy with lanthanum has demonstrated efficacy in controlling phosphorus and maintaining PTH in the target range with less risk of hypercalcemia than calcium-containing binders. 19 Initial daily doses are in the range of 750 to 1,500 mg (administered in divided doses with meals) with doses of 1,500 to 3,000 mg often being required to maintain target phosphorus in ESRD patients. The poor GI absorption, which limits systemic effects, and high binding capacity with phosphorus makes this an attractive phosphate-binding agent, particularly when options other than calcium-containing binders are needed. Lanthanum is available as a chewable tablet, which may be appealing for some patients. Lanthanum carbonate (2,250 to 3,000 mg/day) was as effective in lowering serum phosphorus as sevelamer hydrochloride (4,800 to 6,400 mg/day) in hemodialysis patients. 86 The effect of lanthanum on progression of calcification has not been evaluated in clinical trials.

Aluminum salts were widely used in the 1980s as phosphate-binding agents because of their high binding potency. They should no longer be used as first line agents but rather reserved for acute treatment of severe hyperphosphatemia or used at low doses in combination with either calcium-containing binding agents or sevelamer in cases of hyperphosphatemia that is not responding to therapy with a single agent. According to K/DOQI guidelines, the duration of aluminum therapy should be limited to four weeks if these agents are used at all. 22

Magnesium-containing antacids are also effective phosphate binders and may decrease the amount of calcium-containing binders necessary for control of phosphorus; however, their use is limited by the frequent occurrence of GI side effects (i.e., diarrhea) and the potential for magnesium accumulation.

**Adverse Effects.** Adverse effects of all phosphate binders are generally limited to GI side effects, including constipation, diarrhea, nausea, vomiting, and abdominal pain. The risk of hypercalcemia may necessitate restriction of calcium-containing binders use and/or a reduction in dietary intake. Aluminum binders have been associated with CNS toxicity and the worsening of anemia, whereas magnesium binder use may lead to hypermagnesemia and hyperkalemia.

**Drug–Drug and Drug–Food Interactions.** Calcium-containing phosphate-binding agents interfere with the absorption of several

oral medications that are commonly prescribed for CKD patients, including iron, zinc, and quinolone antibiotics. No drug interaction studies have been performed with sevelamer carbonate; however, studies with sevelamer hydrochloride have shown no drug interactions with digoxin, warfarin, metoprolol, enalapril, or iron. Coadministration with ciprofloxacin did, however, result in a 50% decrease in bioavailability of the antibiotic. This information is reported in the labeling for the newer formulation sevelamer carbonate. Potential interactions between sevelamer and cyclosporine (decreased bioavailability of cyclosporine) and altered phosphorus binding in the presence of agents that increase gastric pH (e.g., omeprazole) have been reported. Drug interaction studies with lanthanum, although limited, have shown that coadministration with warfarin, digoxin, and metoprolol did not affect the bioavailability of those agents. In general, it is rational to separate the administration time of oral medications for which a reduction in bioavailability has a clinically significant effect (e.g., quinolones) from phosphate binders by at least 1 hour before or 3 hours after administration of the phosphate binder. This is a key patient-counseling recommendation as patients are often switched from one phosphate binder to another, and it is easier for them to remember this general concept regarding phosphate binders and other medications. Many phosphate binders are marketed as antacids or calcium supplements, and often CKD patients do not know why they have been prescribed these agents. Regular patient counseling is essential to improve adherence and minimize the potential for drug interactions.

**Dosing and Administration.** Initial dosing regimens for phosphate-binding agents and suggested dose titration schemes are shown in Table 53–8. Doses should be titrated to achieve the recommended serum phosphate concentrations based on the patient’s stage of CKD. The daily dose of elemental calcium should be limited in individuals with elevated calcium levels.

**Vitamin D Therapy** Vitamin D compounds include ergocalciferol (vitamin D3) and cholecalciferol (vitamin D2) that must be converted to the active form in the kidney. Calcitriol (1,25-dihydroxyvitamin D3) is the most active form of vitamin D and is available as an oral formulation (Rocaltor) as well as an IV formulation (Calcijex). The currently available vitamin D analogs include paricalcitol (1α,25-dihydroxyvitamin D3; Zemlara) and doxercalciferol (1α-hydroxyvitamin D3; Hectorol). Calcitriol or one of the vitamin D analogs is required for patients with severe kidney disease because these agents do not require conversion by the kidney to the biologically active form.

**Pharmacology and Mechanism of Action.** Active vitamin D suppresses PTH secretion by stimulating absorption of serum calcium by intestinal cells and through direct activity on the parathyroid gland to decrease PTH synthesis. As a result, the serum calcium concentration is raised and the parathyroid glands decrease the rate of secretion and formation of PTH. The set point for calcium (i.e., the calcium concentration at which PTH secretion is decreased by 50%), which is generally raised in CKD-MBD, is lowered when active vitamin D therapy is initiated. This indicates that a lower ionized calcium concentration is effective at suppressing secretion of PTH. All of these actions are mediated by the interaction of vitamin D with vitamin D receptors, which are located in many organs, including the parathyroid gland, GI tract, and kidney. Calcitriol also upregulates vitamin D receptors, which ultimately may reduce parathyroid hyperplasia. Unfortunately, the enhanced GI absorption of calcium and phosphorus with calcitriol therapy frequently leads to hypercalcemia and hyperphosphatemia. There is also evidence that hyperphosphatemia results in resistance to the PTH-suppressing effects of vitamin D and directly stimulates PTH release. These actions contribute to the increase in the Ca × P product, which is associated with soft-tissue and vascular calcifications. Consequentially, reasonable control of calcium and phosphorus must be achieved before initiation and during continued vitamin D therapy. This does not mean that vitamin D therapy should be withheld or discontinued in patients with a Ca × P product greater than 55 mg²/dL² (4.4 mmol/L²). Rather interventions with agents with a lower risk of hypercalcemia and hyperphosphatemia, and more prudent use of phosphate binders to lower calcium and phosphorus, may be necessary in such patients.

The unique interactions of vitamin D with the vitamin D receptors have been a focus of research and have led to the development of vitamin D analogs, which vary in their affinity for these receptors and result in less hypercalcemia while retaining the positive physiologic actions on bone and parathyroid tissue. Paricalcitol and doxercalciferol are D₃ compounds that effectively lower PTH. Paricalcitol differs from calcitriol by the absence of the exocyclic carbon 19 and the fact that it is a vitamin D₃ derivative. Doxercalciferol is a prohormone that needs to be hydroxylated in the liver to 1,25-dihydroxyvitamin D₃. These agents are available in an IV formulation for use in patients with stage 5 CKD and in oral forms that are approved for use in those with stage 3 to 5 CKD.

**Pharmacokinetics.** Calcitriol can be administered orally as well as by IV injection. Oral absorption occurs rapidly; therefore oral and IV therapies are both reasonable options for treatment of CKD-MBD. When paricalcitol is administered IV, its half-life is similar to that of calcitriol (up to 30 hours). The half-life of paricalcitol after oral administration is 17 to 20 hours in patients with stage 3 and 4 CKD. Doxercalciferol has a slightly prolonged half-life of 45 hours.

**Efficacy.** Administration of calcitriol by either the oral or the IV route may be based on conventional dosing (usually 0.25–0.5 mcg/day) or pulse dosing (0.5–2 mcg two to three times per week). Logistically, IV dosing is more practical in hemodialysis patients, whereas oral therapy is more practical for nondialysis CKD and peritoneal dialysis patients. Conventional daily oral doses of calcitriol may be more frequently associated with hypercalcemia and hyperphosphatemia, because vitamin D receptors are located in intestinal mucosa where direct stimulation can occur.

Although hypercalcemia is less likely with the newer analogs (paricalcitol and doxercalciferol), elevated calcium concentrations have been observed with these agents in patients with ESRD. However, some of these cases were associated with excessive dosing of these agents and oversuppression of PTH, a condition more likely to promote hypercalcemia. When administered at doses 10 times that of calcitriol and at a dose equivalent to doxercalciferol, paricalcitol has been less frequently associated with hypercalcemia in animal studies and in human trials. Intestinal calcium absorption was 14% lower in paricalcitol-treated hemodialysis patients compared with those treated with calcitriol. Doxercalciferol and paricalcitol have also been evaluated in patients with stages 3 and 4 CKD. They are effective in reducing PTH to target levels; however, differences in the magnitude of elevations of calcium and phosphorus have not been directly compared in this population.

Although comparisons between vitamin D analogs are relatively limited the incidence of hyperphosphatemia with paricalcitol was lower than with doxercalciferol when administered at high doses to hemodialysis patients. A more rapid suppression of PTH was also observed in paricalcitol-treated patients compared to those who received calcitriol. The more clinically significant finding from this study was the decrease in incidence of hypercalcemia and elevated Ca × P in the paricalcitol-treated patients. Nontraditional effects of vitamin D, including a potential survival benefit, have also been reported. An improvement in 3-year survival in a large dialysis population receiving paricalcitol was observed compared with a

<sup>a</sup> Multiple preparations are available that are not listed.

historic cohort that received calcitriol.<sup>110</sup> This survival advantage was also observed for hemodialysis patients who received vitamin D (either calcitriol or paricalcitol) compared with no vitamin D and was independent of calcium, phosphorus, and PTH.<sup>111</sup> The relationship between all available vitamin D agents (calcitriol, doxercalciferol, and paricalcitol) and mortality was further evaluated in a retrospective analysis of more than 7,700 hemodialysis patients.<sup>112</sup> After a median follow-up of 37 weeks, all-cause mortality and atherosclerotic cardiovascular mortality were similar for doxercalciferol- and paricalcitol-treated patients and similar to the calcitriol-treated patients when adjusted for laboratory values (e.g., calcium, PTH, albumin, phosphorus) and standardized mortality for the dialysis clinics included in this study. Vitamin D therapy, regardless of agent, was associated with lower mortality. It must be noted that these are observational studies and that prospective, randomized, controlled trials are required to better understand survival benefits associated with vitamin D therapy. Antiproteinuric effects of paricalcitol have also been reported in patients with stages 3 and 4 CKD.<sup>113</sup> These findings are of interest when considering other potential effects of vitamin D beyond suppression of PTH.

**Adverse Effects.** Although all agents are effective in suppressing PTH levels, they differ in the degree to which they cause other metabolic abnormalities. Adverse effects of note with vitamin D therapy in patients treated for CKD-MBD include hypercalcemia and hyperphosphatemia. Differences in calcitriol and vitamin D analogs have been demonstrated in animal studies and in clinical trials evaluating their effect on reduction of PTH while minimizing the risk of these adverse consequences.<sup>115,116</sup>

**Drug–Drug and Drug–Food Interactions.** Cholestyramine may reduce the absorption of orally administered calcitriol and doxercalciferol. In vitro data suggest that paricalcitol is metabolized by the hepatic enzyme CYP3A4 and has the potential to interact with other agents that are metabolized by this enzyme. When ketoconazole, a CYP3A4 inhibitor, was given concomitantly, paricalcitol serum concentrations doubled.<sup>114</sup> Caution is also advised when CYP3A4 inhibitors are given to those receiving doxercalciferol. No other significant interactions have been reported.

**Dosing and Administration.** Recommendations for vitamin D therapy differ based on the stage of CKD. Because deficiency in the vitamin D precursor, 25-hydroxyvitamin D, is common in patients with CKD, K/DOQI guidelines recommend measuring 25-hydroxyvitamin D levels in patients with stage 3 or 4 CKD who have PTH values above the upper recommended ranges (see Table 53–4). If the 25-hydroxyvitamin D level is less than 30 ng/mL (75 nmol/L), a vitamin D precursor (e.g., ergocalciferol or cholecalciferol) is recommended. The dose and duration of treatment are dependent on the severity of the deficiency. To prevent vitamin D insufficiency, doses of 600 to 800 units per day of ergocalciferol are recommended. Calcitriol, doxercalciferol, or paricalcitol should be administered orally when PTH remains elevated despite the achievement of adequate 25-hydroxyvitamin D levels.

Initial oral doses of vitamin D recommended in patients with stage 3 or 4 CKD are 0.25 mcg calcitriol, 1 mcg doxercalciferol, or 1 mg paricalcitol administered daily.<sup>115</sup> For paricalcitol the recommended daily dose is 2 mcg if the PTH is greater than 500 pg/mL (500 ng/L). If these agents are administered intermittently (generally three times per week), the recommended initial oral dose is twice the daily dose. Higher starting doses may be required based on the severity of CKD-MBD. Prior to starting therapy the serum calcium and phosphorus should be within the normal range to minimize the risk of hypercalcemia and an elevated Ca × P. In patients with ESRD there is a clearly defined role for treatment with active vitamin D or a vitamin D analog because the conversion of precursors to active vitamin D is impaired. The active vitamin D agents available in the United States vary markedly with regard to the oral and IV dosage regimens that are recommended for CKD patients (Table 53–9). Serum calcium and Ca × P should be monitored regularly while the patient is receiving therapy. Dose adjustments should be made every 2 to 4 weeks based on PTH concentrations.<sup>12</sup> For patients who need to be converted from calcitriol to paricalcitol, a dosing conversion ratio of 1:4 of IV calcitriol to paricalcitol has been proposed; however, some clinicians suggest a ratio of 1:3 to avoid oversuppression of PTH.

**Calcimimetics**

**Pharmacology and Mechanism of Action.** Cinacalcet hydrochloride (Sensipar) is a calcimimetic agent approved for treatment of secondary hyperparathyroidism in ESRD patients and for treatment of hypercalcemia in patients with parathyroid carcinoma. Cinacalcet is the first agent in this class to receive FDA approval. This compound acts on the calcium-sensing receptor on the surface of the chief cells of the parathyroid gland to mimic the effect of extracellular ionized calcium and increase the sensitivity of the calcium-sensing receptor to calcium, subsequently reducing PTH secretion. Cinacalcet does not increase intestinal calcium and phosphorus absorption. In fact, the reduction in PTH with cinacalcet is associated with a decrease in serum calcium.<sup>116</sup>

**Pharmacokinetics.** The maximum plasma concentration of cinacalcet is achieved in approximately 2 to 6 hours following oral administration. The half-life is approximately 30 to 40 hours. Cinacalcet has a large volume of distribution (approximately 1,000 L), and is 93% to 97% bound to plasma proteins, both characteristics indicating that removal by dialysis is negligible. Cinacalcet is metabolized by the liver, specifically by the cytochrome P450 isoenzymes CYP3A4, CYP2D6, and CYP1A2.<sup>117</sup>
Efficacy. In placebo-controlled clinical trials conducted in dialysis patients (predominantly those receiving hemodialysis) cinacalcet significantly decreased PTH and the Ca × P product within the 6-month study period, regardless of the severity of secondary hyperparathyroidism. The starting dose of 30 mg per day was titrated every 3 or 4 weeks to a maximum dose of 180 mg per day to achieve the target PTH of ≤250 pg/mL (≤250 ng/L) and avoid hypocalcemia. Approximately 66% and 93% of patients in the clinical trials were receiving concurrent vitamin D and phosphate binders, respectively. If a patient experienced symptoms of hypocalcemia or had a serum calcium <8.4 mg/dL (<2.10 mmol/L), calcium supplements and/or calcium-based phosphate binders could be increased. If ineffective, the vitamin D dose could be increased. The median dose required to achieve the desired PTH by the end of the study period was 90 mg. This agent is not approved for use in patients with early stage CKD (stages 3–5 CKD not requiring dialysis) due to the risk of hypocalcemia. Because cinacalcet was approved after the K/DOQI guidelines on bone disease became available, the challenge to clinicians is in deciding how to most effectively use cinacalcet in conjunction with other therapies to manage CKD-MBD. KDIGO guidelines endorse the use of cinacalcet alone or in conjunction with vitamin D therapy to lower PTH in the dialysis population. There are no studies evaluating the effect of cinacalcet on vascular calcification in humans.

Adverse Effects. The most frequently reported adverse events with cinacalcet were nausea and vomiting. Although nausea and vomiting occurred more frequently with cinacalcet, these events were generally transient, mild to moderate in nature, and infrequently led to withdrawal from clinical trials.

Because cinacalcet lowers serum calcium and may cause hypocalcemia, this agent should not be started if the serum calcium is less than the lower limit of normal, approximately 8.4 mg/dL (2.10 mmol/L). Serum calcium should be measured within 1 week after initiation or following a dose adjustment of cinacalcet. Once the maintenance dose is established, serum calcium should be measured approximately monthly. Potential manifestations of hypocalcemia include paresthesia, myalgia, cramping, tetany, and convulsions.

Drug–Drug and Drug–Food Interactions. Because cinacalcet is metabolized by multiple hepatic enzymes there is potential for drug interactions. Cinacalcet is also a potent inhibitor of the enzyme CYP2D6. As a result, dose adjustments of concomitant medications that are predominantly metabolized by this enzyme and have a narrow therapeutic index, such as flecainide, thioridazine, vinblastine, and most tricyclic antidepressants (e.g., amitriptyline) may be required.

Several agents commonly used in the CKD population have been evaluated for interactions with cinacalcet. Coadministration of calcium carbonate or sevelamer did not affect the pharmacokinetics of cinacalcet. Pantoprazole did not alter the pharmacokinetics of cinacalcet. This is an important finding because pantoprazole alters gastric pH, and the solubility of cinacalcet decreases as the gastric pH rises over 5.5. Coadministration of cinacalcet with warfarin also did not affect the pharmacokinetics of warfarin. Coadministration of cinacalcet and ketoconazole, a strong inhibitor of cytochrome P450 (CYP) 3A4, resulted in an increase in the area under the curve and maximum concentration of 2.3 and 2.2 times, respectively. Concurrent administration of cinacalcet with amitriptyline increased amitriptyline exposure and nortriptyline (active metabolite) exposure by approximately 20% in CYP2D6-extensive metabolizers.

Food has been shown to increase absorption of cinacalcet by up to 81% compared with fasting; therefore this medication should be taken with meals to achieve the maximal effect.

Dosing and Administration. The recommended starting oral dose of cinacalcet is 30 mg once daily. The dose should be titrated every two to four weeks to a maximum dose of 180 mg once daily to achieve the desired PTH levels and to maintain near-normal serum calcium concentrations. Patients with hepatic disease may require lower doses, as studies have shown a decrease in metabolism of cinacalcet in this patient population. Cinacalcet is available as a film-coated tablet containing 30, 60, or 90 mg.

Pharmacoeconomic Considerations

Pharmacoeconomic considerations in the management of CKD-MBD and ROD include medication costs, the cost associated with laboratory monitoring, bone biopsies when indicated, and the medical expenditures associated with the management of calcifications and bone fractures. If the associated complications such as vascular and soft-tissue calcifications that may increase morbidity and hospitalizations can be significantly reduced, the additional medication costs may be of minimal consequence.

The pattern of vitamin D product use in U.S. dialysis units has been strongly influenced by Medicare reimbursement. Currently, IV vitamin D products are separately reimbursable expenses for dialysis programs. In fact, dialysis programs often generate significant profit from the IV administration of these agents. In contrast, oral administration of vitamin D is more convenient for patients with stage 3 or 4 CKD and the peritoneal dialysis population; however, these agents are not separately reimbursable. The fact that these agents must be purchased by the patient makes noncompliance with therapy an issue. The payment system for the hemodialysis population is all subject to change as the new “bundling” of payments for dialysis services, designed to reduce financial incentives for utilization of “unnecessary” dialysis services, is implemented in outpatient dialysis facilities (see Pharmacoeconomic Considerations for the anemia management section). In the bundling system currently proposed, the financial reimbursement a dialysis unit receives per dialysis session ($14 per dialysis treatment) would now also include costs of oral drugs such as phosphate binders and cinacalcet. There are concerns in the nephrology community about the effect the new system would have on treatment for CKD-MBD. Dialysis providers may advocate changing patients from more expensive, noncalcemic phosphate binders (e.g., sevelamer carbonate, and lanthanum carbonate) to less expensive calcium-containing binders. Calcitriol, which is more likely to cause hypercalcemia and hyperphosphatemia, may be used more in the ESRD population since both the IV and oral form are less expensive than paricalcitol and doxercalciferol. It is also anticipated that the use of cinacalcet may be reduced because of the cost of this oral calcimimetic. These changes in prescribing to reduce cost burden on dialysis facilities could potentially increase the incidence of hypercalcemia, calcifications, and morbidity in the ESRD population.

CHRONIC METABOLIC ACIDOSIS

Desired Outcome

The goals of therapy for patients with CKD are to normalize the pH of the blood (pH of approximately 7.35–7.45) and maintain the serum bicarbonate within the normal range (22–26 mEq/L [22–26 mmol/L]). In patients on hemodialysis, the goal of therapy is to maintain a predialysis or stabilized bicarbonate concentration at or above 22 mEq/L (22 mmol/L). Metabolic acidosis appears to stimulate protein catabolism, which can contribute to a negative nitrogen balance and lower albumin concentrations. Lower serum bicarbonate levels in peritoneal dialysis patients have also been associated with a higher hospitalization rate and longer hospital stays. Severe acidaemia (blood pH <7.1–7.2) suppresses myocardial contractility, predisposes patients to cardiac arrhythmias, and may lead to a decrease in total peripheral vascular resistance and blood pressure, reduced hepatic
blood flow, and impaired oxygen delivery.\textsuperscript{118} The prevention and treatment of severe metabolic acidosis in patients with kidney disease are also important to prevent the development of CKD-MBD since chronic metabolic acidosis has been shown to alter bone metabolism and decrease the effectiveness of vitamin D therapy.\textsuperscript{22}

**Nonpharmacologic Therapy**

Therapy for metabolic acidosis requires pharmacologic intervention to correct the acidemia. Treatment of other underlying disorders that may be contributory is also warranted.

**Pharmacologic Therapy**

In patients with stage 4 or 5 CKD, the use of alkalinizing salts, such as sodium bicarbonate or citrate/citric acid preparations, is useful to replenish depleted body bicarbonate stores. Sodium bicarbonate tablets are manufactured in 325- and 650-mg strengths (a 650-mg tablet contains 7.6 mEq [7.6 mmol] sodium and 7.6 mEq [7.6 mmol] bicarbonate). Shoel solution and Bicita contain 1 mEq/mL (1 mmol/mL) of sodium and the equivalent of 1 mEq/mL (1 mmol/mL) of bicarbonate as sodium citrate/citric acid. Citrate is metabolized in the liver to bicarbonate, and citric acid is metabolized to CO\textsubscript{2} and water. Polycitra, which contains potassium citrate (1 mEq/mL [1 mmol/mL]) of sodium, 1 mEq/mL [1 mmol/mL] of potassium, and 2 mEq/mL [2 mmol/mL] of bicarbonate) should not be used in patients with severe CKD because of the risk of hyperkalemia.

The replacement dose of alkali (base) needed to restore the serum bicarbonate concentration to normal (24 mEq/L [24 mmol/L]) can be approximated by multiplying the volume of distribution of bicarbonate (0.5 L/kg) by the patient’s body weight (in kilograms) and the patient’s base deficit (difference between the patient’s serum bicarbonate value and the normal value of 24 mEq/L [24 mmol/L]). The calculated amount of bicarbonate replacement therapy (in milliequivalents [or in mmols]) should be administered over several days to prevent volume overload from excessive sodium intake. After the serum bicarbonate has normalized, a maintenance regimen of bicarbonate to neutralize daily acid production may be all that is necessary (12 to 20 mEq/day [12 to 20 mmol/day] in divided doses). Doses are subsequently titrated to maintain normal plasma bicarbonate concentrations. Patients with renal tubular acidosis may require higher doses of alkalinizing agents (see Chap. 61). Fluid balance should be monitored carefully because of the sodium content of these agents. Citrate-containing solutions should not be used in combination with aluminum-containing compounds because they can enhance aluminum absorption and increase the risk of aluminum intoxication. Excessive doses of alkalinizing agents may cause metabolic alkalosis, as well as lethargy or cardiac depression secondary to a decrease in ionized serum calcium concentration. Gastrointestinal distress characterized by gastric distension and flatulence is relatively common with high doses of oral sodium bicarbonate. Patients with severe acidemia (serum bicarbonate <8 mEq/L [<8 mmol/L]; pH <7.2) will likely require IV therapy (see Chap. 61).

Metabolic acidosis in both adult and pediatric patients undergoing dialysis is usually managed by tailoring the patient’s dialysis prescription. Increasing the concentration of bicarbonate (or acetate) in the dialysate to values above the serum bicarbonate concentration causes diffusion of the bicarbonate across the dialyzer and is an effective chronic treatment for metabolic acidosis in the dialysis population (see Chap. 54). Administration of oral bicarbonate salts may also be necessary for some dialysis patients.

**Evaluation of Therapeutic Outcomes**

Regular monitoring of serum electrolytes and arterial blood gases is necessary to determine the effectiveness of therapy. A gradual correction of serum bicarbonate is appropriate to avoid overcorrection and subsequent complications such as alkalosis and other electrolyte abnormalities (see Chap. 61). Laboratory measurement of serum bicarbonate is associated with several technical problems. Blood collection techniques, transportation, and assay methodology can affect the measured concentrations. Blood samples should not have contact with air, process delays should be avoided, and consistent analytical methods should be used with serial measurements to improve accuracy.\textsuperscript{5}

### CARDIOVASCULAR DISEASE

Specific recommendations regarding the management of cardiovascular disease in the ESRD population are included in K/DOQI guidelines. This includes recommendations for management of coronary artery disease, acute coronary syndromes, valvular heart disease, cardiomyopathy, dysrhythmias, cerebrovascular disease, and peripheral vascular disease. Differences in management of these disorders in dialysis patients compared with the general population are emphasized. Guidelines for management of cardiovascular risk factors are also included. Two of the most common medication amenable risk factors for cardiovascular disease in the CKD population—hypertension and hyperlipidemia—are discussed here.

**Desired Outcome**

**Hypertension**

The goal blood pressure for cardiovascular risk reduction in patients with early-stage CKD is less than 130/80 mm Hg.\textsuperscript{118} The target blood pressure in patients with ESRD is not well defined; however, the K/DOQI guidelines propose a predialysis blood pressure of less than 140/90 mm Hg and a postdialysis blood pressure of less than 130/80 mm Hg, although this recommendation is not based on data from prospective, controlled studies.\textsuperscript{5} The targets may need to be individualized for patients who experience intradialytic hypotension (hypotension during the hemodialysis process). These goals can rarely be achieved using lifestyle modifications alone and aggressive antihypertensive therapy is often required.

**Hyperlipidemia**

Based on strong evidence of risk reduction and the benefits of lipid-lowering therapy in the general population, the consensus is that CKD patients are among the highest-risk group for cardiovascular conditions (i.e., equivalent to that of patients with known coronary heart disease) and should be treated aggressively for dyslipidemia to an LDL cholesterol goal below 100 mg/dL (2.59 mmol/L).\textsuperscript{41,119} The decision to lower LDL cholesterol to less than 70 mg/dL (1.81 mmol/L) based on more recent data in high-risk populations is a therapeutic option, although this approach is not supported by strong evidence from clinical trials in CKD.

Table 53–10 lists the goals and suggested course of therapy based on the K/DOQI guidelines for patients with stage 5 CKD based on their lipid abnormality.

**Nonpharmacologic Therapy**

**Hypertension**

Fluid intake should be limited in patients with volume overload, particularly in patients on hemodialysis who are at risk for substantial fluid accumulation between dialysis sessions. Regular dietary counseling is critical to the success of nonpharmacologic interventions, given the large number of lifestyle changes typically required by CKD patients. Other lifestyle modifications, including regular exercise, weight loss, and smoking cessation, are also recommended but difficult to implement.

A primary nonpharmacologic intervention for management of hypertension in patients with ESRD is sodium restriction to approximately 2 g/day. In hemodialysis patients, achievement of an individual’s “dry weight” is necessary to control blood pressure and may be done through dietary intervention, increased
Dyslipidemia | Goal | Initial Therapy | Modification in Therapy | Alternative
---|---|---|---|---
TG ≥500 mg/dL (≥5.56 mmol/L) | TLC | TLC + fibrate or niacin | Fibrate or niacin
LDL 100–129 mg/dL (2.56–3.34 mmol/L) | TLC | TLC + low-dose statin | Fibrate or niacin
LDL ≥130 mg/dL (≥3.36 mmol/L) | TLC | TLC + low-dose statin | Fibrate or niacin
TG ≥200 mg/dL (≥2.26 mmol/L) and Non-HDL ≥130 mg/dL (≥3.36 mmol/L) | Non-HDL <150 mg/dL (≤3.81 mmol/L) | TLC + maximum-dose statin | Fibrate or niacin

HDL, high-density lipoprotein; LDL, low-density lipoprotein; Non-HDL, total cholesterol minus HDL cholesterol; TG, triglycerides; TLC, therapeutic lifestyle changes.

Hyperlipidemia

- In patients with elevated triglyceride levels (≥500 mg/dL [≥5.65 mmol/L]) and/or LDL between 100 and 129 mg/dL (2.56–3.34 mmol/L), lifestyle changes without pharmacologic therapy are recommended as initial therapy (see Chap. 28). Unfortunately, most patients with CKD have already been advised to adhere to difficult dietary regimens, which may include protein, phosphorus, sodium, potassium, and fluid restrictions. Thus, although diet therapy is a reasonable first-step approach, it may not be successful in many patients with CKD because of noncompliance. A diettian who is well versed in the management of kidney disease should be consulted.

**Pharmacologic Therapy**

**Hypertension**

Most patients with hypertension and advanced CKD (GFR <30 mL/min/1.73 m² [≤0.29 mL/s/m²]) require three or more antihypertensive agents to achieve target blood pressure. **Blood pressure reductions can be achieved with agents in all anti-hypertensive classes, although there is a preference for agents that inhibit the renin–angiotensin system, and choice should be guided by the individual patient’s comorbid disease states.**

Diuretic therapy is beneficial for management of blood pressure in patients with early CKD; however, thiazide diuretics are not generally effective in patients with a GFR of <30 mL/min (<0.50 mL/s). Loop diuretics can be used throughout all stages of CKD; however, patients with ESRD who have minimal to no residual kidney function will often not respond to these agents.

ACEIs or angiotensin receptor blockers are the preferred agents for patients with progressive CKD and proteinuria. They are also preferred in certain patients with ESRD because of their potential benefits including regression of LVH, reduction in sympathetic nerve activity and pulse-wave velocity, improvement in endothelial function, and reduced oxidative stress. Lower initial doses of these agents may be necessary because the elimination half-lives of the parent compound (captopril and lisinopril) or active metabolite (enalapril, benazepril, and ramipril) are prolonged in ESRD patients. Available angiotensin receptor blockers do not require dosage adjustment for decreased kidney function, and they are not effectively removed by hemodialysis.

Calcium channel blockers that selectively lower systemic vascular resistance also appear to be effective in the treatment of hypertension in patients with ESRD and are associated with decreased total and cardiovascular mortality. β-Blockers may be particularly useful in hypertensive CKD patients given the beneficial effects after myocardial infarction. Agents such as esmolol, timolol, pindolol, metoprolol, and labetalol, which are metabolized and not significantly removed by dialysis, may be easier to dose titrate than agents that are both dialyzable and extensively eliminated unchanged by the kidney (e.g., acebutolol, atenolol, bisoprolol, and nadolol). Agents requiring less-frequent dosing may be used to improve patient compliance.

Use of other antihypertensive agents in the patient with CKD should be based on recommendations in the general population (see Chap. 19). In the ESRD population, agents that act on the sympathetic nervous system, such as prazosin, terazosin, doxazosin, clonidine, guanabenz, and guanfacine, may be required in patients who are unresponsive to ACEIs, calcium channel blockers, or β-blocker therapy, and used in conjunction with adequate dialysis. Central α₁-agonists such as clonidine appear to be the safest of these agents; however, adverse effects, such as dry mouth, may lead to extra fluid consumption in some patients. Postsynaptic α-blockers (e.g., prazosin) are associated with postural hypotension following hemodialysis. Guanethidine and methyldopa should be avoided because of potential complications, including severe postural hypotension, severe dialysis-related hypotension, and impotence. The addition of vasodilators such as minoxidil may prove useful in patients resistant to combinations of the previously mentioned agents.

Based on claims data from the USRDS approximately 75% of stage 3 to 5 CKD patients with hypertension (excluding the ESRD population) received an ACEI or angiotensin receptor blocker within a year after diagnosis of CKD. The data also indicated that β-blockers and nondihydropyridine calcium channel blockers were used in approximately 50% and 40% of CKD patients, respectively. Loop diuretic use was reported in approximately 40% of stage 3 to 5 CKD patients and thiazide-like diuretics were prescribed for approximately 35%.

**Hyperlipidemia**

Management of dyslipidemia in patients with CKD is based on the report from the National Cholesterol Education Program and the K/DOQI guidelines for dyslipidemia in patients with CKD." If lifestyle changes are not effective in achieving goal triglyceride and LDL levels after a few months, drug therapy is warranted (see Table 53–10 and Chap. 28). Drug therapy is also recommended for those with more extreme elevations in LDL (≥130 mg/dL [≥3.36 mmol/L]).

Drug classes that may prove useful in treatment of lipid disorders include 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins), bile acid sequestrants, nicotinic acid, and fibric acids (gemfibrozil and clofibrate). Statins are the most effective drugs for lowering LDL and total cholesterol in patients with kidney disease (with or without nephrotic syndrome) and generally should be regarded as the drugs of first choice, keeping in mind the controversies in the ESRD population (see below). Drug therapy for hypertriglyceridemia includes a fibrate or nicotinic acid; in general, fibrates are better tolerated. Patients receiving sevelamer as a phosphate binder may also benefit from its cholesterol-lowering effects.
Several potential drug interactions and/or adverse effects have been observed in those CKD patients receiving antilipemic therapy. The nonselective binding activity of bile acid sequestrants may reduce absorption of corticosteroids, digoxin, thiazide diuretics, warfarin, and other commonly used medications. Myositis and myalgia, along with increased serum creatine phosphokinase (CPK), may occur in ESRD patients who use clofibrate. Determining the optimal dose of clofibrate in this patient population is difficult as plasma protein-binding changes markedly affect free concentrations of the active metabolite clofibrinic acid, which has a prolonged half-life in patients with stage 5 CKD. Gemfibrozil may be a safer alternative, as the half-life is not altered with kidney dysfunction. Lower doses of 300 mg twice a day with close monitoring of CPK are recommended by some clinicians, based on an association of standard dose therapy with increases in CPK concentrations in dialysis patients.

Although statins are remarkably free of adverse effects in otherwise healthy subjects, one should be cognizant of the potential myotoxic effects of these drugs, especially when administered with interacting agents, such as azole antibiotics, cyclosporine, gemfibrozil, and niacin, and in the presence of hepatic disease. There is increased risk of rhabdomyolysis with combined fibrate and statin therapy in patients with CKD, and diligent monitoring by prescribers and patients is necessary. Dose reductions are warranted for lovastatin and rosuvastatin in stage 4 CKD and simvastatin in ESRD patients because of their reduced renal elimination.

**Statins in Early-Stage CKD.** Statins are effective agents in patients with early-stage CKD, although there is little documented clinical trial data. Atorvastatin therapy targeted to achieve an LDL of 80 mg/dL (2.07 mmol/L) or a maximum dose of 80 mg per day decreased cardiovascular risk in individuals with coronary heart disease and stage 3 CKD. This effect was similar to that achieved in individuals without CKD. These results are similar to those from the Treating to New Targets trial, which evaluated atorvastatin (80 mg vs 10 mg per day) on cardiovascular events in patients with \( n = 3,107 \) and without \( n = 6,549 \) CKD. Atorvastatin 80 mg reduced the relative risk of major cardiovascular events by 32% in patients with CKD over the median follow-up period of 5 years. Thus statin therapy clearly can reduce cardiovascular risk for patients with stage 3 CKD. Evidence of these benefits for those with stage 4 CKD, however, is lacking.

**Statins in the ESRD Population.** Data on statin use in the ESRD population are not consistently favorable as they are in early CKD. Although observational studies in hemodialysis patients receiving statins indicated a significant benefit: 31% relative risk reduction in overall mortality and a 23% reduction in cardiac causes of death, the findings from prospective studies have not been encouraging. Results from a 4-year study evaluating the effect of atorvastatin therapy on cardiac mortality in more than 1,200 hemodialysis patients with type 2 diabetes showed no significant benefit in the composite end point compared with the placebo group. In fact, there was a significantly greater relative risk of fatal stroke in the atorvastatin-treated patients. These findings do not support initiation of statin therapy in ESRD patients, especially those with type 2 diabetes. The AURORA trial assessed the impact of rosvastatin 10 mg daily or placebo on the primary end points of death from cardiovascular causes, nonfatal MI, or nonfatal stroke. Despite a 43% reduction in cholesterol in the rosuvastatin group there was no difference in the primary end points. It is evident from these trials that information from the general population regarding statin therapy cannot be directly extrapolated to the ESRD population. Results from an ongoing trial known as the Study of Heart and Renal Protection (SHARP) trial will provide additional information on the use of the combination of simvastatin and ezetimibe both in those with early-stage CKD as well as in hemodialysis patients.

### CLINICAL CONTROVERSY

While observational studies have reported decreased mortality associated with statin use in the dialysis population, this has not been demonstrated in prospective trials (4D and AURORA trials). Critics of these prospective trials argue that these trials included patients with preexisting cardiovascular disease (e.g., history of MI) and speculate whether a study designed for primary prevention of cardiovascular events would have yielded positive results. There is also the argument that LDL cholesterol levels in the populations studied were relatively low and the effect of statins in individuals with higher LDL cholesterol levels (above 150 mg/dL [3.88 mmol/L]) was not adequately studied. For these reasons some practitioners support use of statins for primary prevention of cardiovascular events in the dialysis population and for individuals with LDL cholesterol levels well above 150 mg/dL (3.88 mmol/L).

#### Pharmacoeconomic Considerations

**Hypertension** Compliance and economic factors must be considered in the selection of antihypertensive therapy for CKD patients. Patients with ESRD are prescribed a median of eight medications. Choosing agents that can be administered once or twice daily may improve patient compliance. In addition, there are now many options within some antihypertensive classes such as calcium channel blockers, ACEIs, angiotensin receptor blockers, and β-blockers, which allow for less-frequent dosing. In most cases, no clear therapeutic advantage has been demonstrated with any particular agent within a class. Therefore, selecting the least costly agent that can be administered once or twice daily is reasonable.

A meta-analysis of studies done in the hemodialysis population evaluating the effect of blood pressure lowering on cardiovascular outcomes showed that blood pressure lowering was associated with a decreased risk of cardiovascular events and all-cause cardiovascular mortality. As more information becomes available from studies evaluating the effects of long-term therapy of hypertension on cardiovascular events in patients with CKD, cost benefits from potentially decreasing the occurrence of such events and their comorbidities may be quantified.

**Hyperlipidemia** Statin therapy for treatment of dyslipidemias has been shown to be cost-effective in patients at high risk for coronary heart disease. Although this has not specifically been evaluated in patients with CKD, this population is considered in the highest-risk group for coronary heart disease and cardiovascular events. It may be reasonable, at least in theory, to extrapolate this information on the cost benefits of therapy to the CKD population, although findings from the trials in the ESRD population contradict this rationale.

#### Evaluation of Therapeutic Outcomes

**Hypertension** Blood pressure monitoring to determine the effectiveness of therapy should be done at each clinic visit, particularly following initiation of therapy (nonpharmacologic or pharmacologic), and at home when feasible. Patients on hemodialysis should have blood pressure measured before, during, and after dialysis to determine the effect of changes in their volume status on blood pressure. Some hemodialysis patients experience a paradoxical rise in blood pressure during dialysis. In these cases, the effect of dialysis...
on removal of antihypertensive agents and the dosing times relative to the dialysis procedure need to be evaluated. Similarly, patients may need to adjust the time of administration of antihypertensive therapy relative to the dialysis session if intradialytic hypertension occurs. Such decisions should be based on the pharmacokinetic profile of the antihypertensive agent in patients with ESRD. Chapter 19 discusses more specifics of monitoring blood pressure and associated complications.

Hyperlipidemia Patients should have their lipid profile reassessed 2 to 3 months following a change in treatment and at least annually thereafter. Periodic evaluations of cardiovascular performance, as described in Chapters 17 and 28, are also warranted.

OTHER COMPLICATIONS

Nutritional Status

Protein-energy malnutrition is very common among patients with advanced CKD (stages 4 and 5). Causes of malnutrition in these patients include inadequate food intake secondary to anorexia, altered taste sensation, and the unpalatability of prescribed diets. Other factors in the ESRD population, such as the effect of the dialysis procedure on removal of nutrients, hypercatabolism induced by other inflammatory conditions, and blood loss are also contributory. Protein restriction as an intervention to potentially delay progression of kidney disease in patients with stage 3 or 4 CKD may also lead to protein malnutrition by the time a patient reaches ESRD; therefore the risks versus the benefits of this intervention must be considered on an individual basis (see Chap. 52) as hypoalbuminemia and malnutrition have a strong association with mortality in chronic dialysis patients.

Patients with ESRD have increased nutritional needs relative to the general population, based on the effect of the disease state and the dialysis procedure on nutritional status. The recommended dietary protein intake in chronic hemodialysis patients is 1.2 g/kg body weight per day. The recommended intake for chronic peritoneal dialysis patients is at least 1.2 to 1.3 g/kg body weight per day, based on the increased protein loss that occurs with this dialysis modality. Protein requirements are higher in patients who are acutely ill (see Chap. 149). The recommended total daily energy intake in both hemodialysis and peritoneal dialysis patients is 35 kcal/kg (147 kJ/kg) body weight per day. For peritoneal dialysis patients, this includes intake from both diet and the glucose absorbed from peritoneal dialysate. For patients older than 60 years of age this criterion differs, because increasing age is generally associated with reduced physical activity and lean body mass. Daily energy intake for these patients is 30 to 35 kcal/kg (126–147 kJ/kg) body weight per day. Nutritional support should be considered for those patients who cannot achieve these goals with oral intake alone. Another option for nutritional supplementation in patients on hemodialysis includes interdialytic parenteral nutrition (see Chap. 151).

Vitamin requirements for ESRD patients receiving dialysis differ from those of a healthy person because of dietary modifications, kidney dysfunction, and dialysis therapy. The plasma concentrations of vitamins A and E are elevated in ESRD, whereas those of the water-soluble vitamins (B₁₂, B₆, B₉, niacin, pantethenic acid, folic acid, biotin, and vitamin C) tend to be low in large part because many are dialyzable. The goal for vitamin supplementation should be to prevent subclinical and frank deficiency and to avoid pathology from overdosage. Special vitamin supplements have been formulated for the dialysis population, which primarily include B vitamins with C and folic acid.

Supplementation with L-carnitine has been advocated for its potential benefits in patients with ESRD, including management of hypertriglyceridemia, hypercholesterolemia, and anemia.

Although some of these benefits have been demonstrated, the evidence does not strongly support routine supplementation. Cost and the addition of yet another medication to the already complex regimen prescribed for many of these patients also mitigate against the routine use of this agent.

Uremic Bleeding

Bleeding complications in patients with CKD are usually mild but can result in major hemorrhagic events. The primary mechanisms underlying the hemostatic problem are platelet biochemical abnormalities and alterations in platelet–vessel wall interactions. Decreased platelet aggregation and adhesiveness have been shown in a number of studies in ESRD patients. Additionally, there is a decreased plasma concentration and defective binding of the large multimer of von Willebrand factor, which results in abnormal platelet–blood vessel wall interactions. Patients on hemodialysis are at even greater risk of bleeding, not only because of the hemodialysis process itself but from administration of other medications. Heparin is frequently administered during dialysis procedures to prevent clotting during dialysis. Patients who are at high risk for bleeding may require alternative anticoagulation procedures rather than traditional hemodialysis with systemic heparinization. In addition, dialysis patients often receive systemic anticoagulation (warfarin) or antiplatelet therapy (aspirin or clopidogrel) for prevention of access clotting or other cardiovascular disorders. This complication is discussed in additional detail in Chapter 54.

CONCLUSIONS

The number of patients with and at risk for CKD is increasing, with a substantial rise in the population with stage 5 CKD expected in the next decade. Although efforts to delay progression of CKD are paramount, measures to diagnose and manage the associated secondary complications and comorbid conditions early in the course of the disease are also essential. Common complications of stages 4 and 5 CKD include anemia, CKD-MBD and renal osteodystrophy, fluid and electrolyte abnormalities, metabolic acidosis, and malnutrition. Cardiovascular complications are also prevalent in the population with CKD, and are the leading cause of mortality in patients with stage 5 disease. Patient education plays a critical role in the appropriate management of CKD and related complications.

A multidisciplinary team structure is a rational approach to providing this education and effectively designing and implementing the required extensive nonpharmacologic and pharmacologic interventions. Pharmacists are among the healthcare providers who contribute substantially to this team as shown by their activities in identifying and resolving drug-related problems, improving patient adherence with drug therapy, and providing more cost-effective medication use in dialysis facilities. There are many opportunities for pharmacists to become involved in both the outpatient dialysis or ambulatory care settings as well as the inpatient environment to improve the management of patients with CKD and the associated complications.

ABBREVIATIONS

ACEI: Angiotensin-converting enzyme inhibitor
ABPM: Ambulatory blood pressure monitoring
AIDS: Acquired immunodeficiency syndrome
ARIC: Atherosclerosis Risk in Communities study
Ca × P: Calcium phosphorus product; serum calcium multiplied by serum phosphorus
CPK: Creatine phosphokinase
CPMs: Clinical performance measures
CMS: Centers for Medicare and Medicaid Services
CKD: Chronic kidney disease
DRPs: Drug-related problems
eGFR: Estimated glomerular filtration rate
EBCT: Electron-beam computed tomography
ESA: Erthropoietic-stimulating agent
ESRD: End-stage renal disease
FE\textsubscript{K}: Fractional excretion of potassium
FE\textsubscript{N}: Fractional excretion of sodium
GFR: Glomerular filtration rate
Hb: Hemoglobin
HCT: Hematocrit
HDL: High-density lipoprotein
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A (reductase)

K/DOQI: Kidney Disease Outcomes Quality Initiative
LDL: Low-density lipoprotein
LVH: Left ventricular hypertrophy
MBD: Mineral and bone disorder
MTM: Medication therapy management
PRCA: Pure red cell aplasia
PTH: Parathyroid hormone
RDS: Renal osteodystrophy
SHARP: Study of Heart and Renal Protection
sHPT: Secondary hyperparathyroidism
TREAT: Trial to Reduce Cardiovascular Events with Aranesp Therapy
TSat: Transferrin saturation
USRD: United States Renal Data System

REFERENCES

KEY CONCEPTS

1. The hemodialysis procedure involves the perfusion of blood and dialysate on opposite sides of a semipermeable membrane. Substances are removed from the blood by diffusion and convection. Excess plasma water is removed via ultrafiltration.

2. The native arteriovenous fistula is the preferred access for hemodialysis because of fewer complications and a longer survival rate. Venous catheters are plagued by complications such as infection and thrombosis and often deliver relatively poor blood flow rates.

3. Adequacy of hemodialysis can be assessed by the Kt/V and urea reduction ratio (URR). The National Kidney Foundation’s Kidney Disease Outcomes Quality Initiative has set the minimum goal Kt/V at greater than 1.2 per treatment and the URR at greater than 65%. In practice, most patients on hemodialysis exceed this goal.

4. During hemodialysis, patients commonly experience hypotension and cramps. Other more serious complications include infection and thrombosis of the vascular access.

5. The peritoneal dialysis procedure involves the instillation of dialysate into the peritoneal cavity via a permanent peritoneal catheter. The peritoneal membrane lines the highly vascularized abdominal viscera and acts as the semipermeable membrane across which diffusion and ultrafiltration occur. Substances are removed from the blood across the peritoneum via diffusion and ultrafiltration. Excess plasma water is removed via ultrafiltration created by osmotic pressure generated by various dextrose or icodextrin concentrations.

6. Patients on peritoneal dialysis are required to instill and drain, manually or via automated systems, several liters of fresh dialysate each day. The more exchanges a patient completes each day, the greater the solute removal.

7. Patients on peritoneal dialysis are required to instill and drain, manually or via automated systems, several liters of fresh dialysate each day. The more exchanges a patient completes each day, the greater the solute removal.

8. Nasal carriage of Staphylococcus aureus is associated with an increased risk of catheter-related infections and peritonitis. Prophylaxis with intranasal mupirocin (twice a day for 5 days every month) or mupirocin (daily) at the exit site can effectively reduce S. aureus infections.

The three primary treatment options for patients with end-stage renal disease (ESRD) are hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data System (USRDS) is the national system that “collects, analyzes, and distributes” data relating to patients with ESRD or stage 5 chronic kidney disease (CKD) in the U.S. According to the 2009 USRDS, at the end of 2007, there were more than 527,000 patients in the United States with ESRD. Of these, 341,264 and 26,340 patients were being treated with HD and PD, respectively, and 151,502 had a functioning kidney transplant. In 2007, nearly 111,000 new patients started therapy for ESRD (dialysis or transplantation) and over 88,000 patients died. The vast majority of new dialysis patients are treated with HD. The number of patients treated with PD has decreased by over 7% since 2000. Although the number of patients who have received a kidney transplant has risen steadily, transplantation has not kept pace with the growing prevalence of ESRD in the United States.
Drug-Induced Kidney Disease

KEY CONCEPTS

1. The initial diagnosis of drug-induced kidney disease typically involves detection of elevated serum creatinine and blood urea nitrogen, for which there is a temporal relationship between the toxicity and use of a potentially nephrotoxic drug.

2. Drug-induced kidney disease is best prevented by avoiding the use of potentially nephrotoxic agents for patients at increased risk for toxicity. However, when exposure to these drugs cannot be avoided, recognition of risk factors and specific techniques, such as hydration, may be used to reduce potential nephrotoxicity.

3. Acute tubular necrosis is the most common presentation of drug-induced kidney disease in hospitalized patients. The primary agents implicated are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, and osmotically active agents.

4. Angiotensin-converting enzyme inhibitors and nonsteroidal antiinflammatory drugs are associated with hemodynamically-mediated kidney injury, the pathogenesis of which is a decrease in glomerular capillary hydrostatic pressure.

5. Acute allergic interstitial nephritis is observed in up to 27% of kidney biopsies performed for hospitalized patients with unexplained acute kidney injury. Clinical manifestations of allergic interstitial nephritis typically present approximately 14 days after initiation of therapy and include fever, maculopapular rash, eosinophilia, arthralgia, often with pyuria, hematuria, proteinuria, and oliguria.

Numerous diagnostic and therapeutic agents have been associated with the development of drug-induced kidney disease (DIKD) or nephrotoxicity. It is a relatively common complication with variable presentations depending on the drug and clinical setting, inpatient or outpatient. Manifestations of DIKD include acid–base abnormalities, electrolyte imbalances, urine sediment abnormalities, proteinuria, pyuria, and/or hematuria.1 However, the most common manifestation of DIKD is a decline in the glomerular filtration rate (GFR), which results in a rise in serum creatinine ($S_c$) and blood urea nitrogen (BUN) and several other indicators of acute and chronic kidney injury (see Chaps. 50 and 51). Initial diagnosis of DIKD is often delayed as it typically is based on the detection of elevated $S_c$ and BUN, for which there is a temporal relationship between the kidney injury and exposure to the potentially nephrotoxic drug. This is consistent with classic qualitative definitions of acute renal failure, which have relied on either an abrupt increase in $S_c$ or an abrupt decline in urine output (see Chaps. 50 and 51).2 The clinical use of numerous definitions of acute renal failure and nephrotoxicity based on quantitative changes in the $S_c$ concentration and other clinical end points made it extraordinarily difficult to ascertain their true incidence.3 Relatively new diagnostic criteria based on a combination of physiologic measurements (e.g., $S_c$ and urine output) have been recently introduced and are now being incorporated into clinical practice and research.4 This has resulted in replacement of the term acute renal failure with acute kidney injury (AKI) and will likely lead to epidemiologic data about DIKD that are more accurate in the future.

Nephrotoxicity is often reversible if one discontinues the use of the offending agent, but in some cases there may still be an AKI and progression to stage 5 chronic kidney disease (CKD) which is also termed end-stage renal disease (ESRD). Currently, many different mechanisms are responsible for the pathogenesis of DIKD, and the introduction of new drugs with novel mechanisms of action provides the potential for the identification of new presentations of AKI and CKD. This chapter reviews the epidemiology, pathophysiology, risk factors, and basic principles of prevention of DIKD. Detailed discussions of these issues plus management strategies are presented for the most commonly used agents that have been associated with a moderate to high likelihood of DIKD.

EPIDEMIOLOGY

The incidence and characteristics of outpatient or community-acquired DIKD are not well understood since mild toxicity is often unrecognized in this setting. However, the acquisition of data regarding the pharmacoepidemiology of these effects has become more important as care increasingly shifts to the outpatient setting. The incidence of community-based AKI that required dialysis was recently reported to be 29.5 per 100,000 person years and 522.4 per 100,000 person years for patients not requiring dialysis.7 Although the incidence of drug-induced AKI was not specifically reported, earlier studies have implicated community-acquired DIKD in up to 20% of hospital admissions due to AKI.8 Conversely, AKI has been reported in up to 7% of hospitalized patients,9 and as many as 20% to 30% of critically ill patients may experience AKI during their hospitalization.10,11 Drug-induced causes have been implicated in up to 60% of all cases of in-hospital AKI and as such are a recognized source of significant morbidity and mortality.9 Although the incidence of in-hospital antibiotic-induced AKI alone
has been reported to be as high as 36%, it appears to be declining, while cases of in-hospital AKI due to nonselective nonsteroidal antiinflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors (ACEIs), chemotherapeutic agents, and antiviral drugs are increasing.

### CLINICAL PRESENTATION OF DRUG-INDUCED KIDNEY DISEASE

#### General
- The most common manifestation is a decline in GFR leading to a rise in $S_e$ and BUN.
- Alterations in renal tubular function without loss of glomerular filtration may be evident.

#### Symptoms
- Patients may complain of malaise, anorexia, vomiting, shortness of breath, or edema, particularly in the outpatient setting.

#### Signs
- Decreased urine output may be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs, with progression to volume overload and hypertension.
- Proximal tubular injury: Metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium due to increased urinary losses.
- Distal tubular injury: Polyuria from failure to maximally concentrate urine, metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.

#### Laboratory Tests
- An abrupt (within 48 hours) reduction in kidney function defined as an absolute increase in $S_e$ of $\geq$0.3 mg/dL ($27 \mu$mol/L), a percentage increase in $S_e$ of $\geq$50% (1.5-fold from baseline), or a reduction in urine output (documented oliguria of less than 0.5 ml/kg per hour for more than 6 hours) [13] when correlated temporally with the initiation of drug therapy may indicate drug-induced AKI.

#### Other Diagnostic Tests
- Urinary excretion of N-acetyl-$\beta$-D-glucosaminidase, $\gamma$-glutamyl transpeptidase, glutathione S-transferase, and interleukin (IL)-18 are markers of proximal tubular injury and have been used for the early detection of AKI in critically ill patients.
- Kidney injury molecule-1 (KIM-1) is expressed in the proximal tubule and is upregulated for patients with ischemic acute tubular necrosis, appearing in the urine within 12 hours after the ischemic insult.
- Neutrophil gelatinase-associated lipocalin (NGAL) protein may be detected in the urine within 3 hours of ischemic injury.

PRINCIPLES FOR PREVENTION OF DRUG-INDUCED NEPHROPATHY

The primary principle for prevention of DIKD is to avoid the use of nephrotoxic agents for patients at increased risk for toxicity. Therefore, an awareness of potentially nephrotoxic drugs and knowledge of risk factors that increase renal vulnerability is essential. Exposure to these drugs often cannot be avoided, so several interventions have been proposed to reduce the potential for the development of nephrotoxicity, for example, adjustment of medication dosage regimens based on accurate estimates of renal function, and careful and adequate hydration to establish high urine flow rates. Other preventative strategies are still theoretical and/or investigational and relate directly to the specific nephrotoxic mechanisms of a given drug. For example, cidofovir and adefovir are antiretroviral drugs that are actively transported by human organic anion transporter 1 (OAT1). Competitive inhibition of OAT1-mediated transport with probenecid minimizes intracellular accumulation of cidofovir and adefovir in renal proximal tubule cells and reduces the likelihood of nephrotoxicity.

Table 55–1 lists the several specific drug-induced renal structural–functional alterations that are responsible for the vast majority of cases of DIKD. This chapter discusses the pathophysiological mechanisms responsible for the development of DIKD with these agents in detail, along with clinical presentation, prevention strategies, therapeutic management approaches, and relevant monitoring plans.

TUBULAR EPITHELIAL CELL DAMAGE

Drugs that lead to renal tubular epithelial cell damage typically do so via direct cellular toxicity or ischemia. Damage is most often localized in the proximal and distal tubular epithelia and is termed acute tubular necrosis (ATN) when cellular degeneration and sloughing from proximal and distal tubular basement membranes are observed. This classically manifests as cellular debris-filled, muddy-brown, granular casts in the urinary sediment. Specific indicators of proximal tubular injury include metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium as a result of increased urinary losses. Indicators of distal tubular injury include polyaury from failure to maximally concentrate urine (i.e., nephrogenic diabetes insipidus), metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion. ATN is the most common presentation of DIKD in the inpatient setting. The primary agents associated with this type of injury are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarin, and osmotically active agents such as immunoglobulins, dextran, and mannitol.

ACUTE TUBULAR NECROSIS

Aminoglycoside Nephrotoxicity

Incidence Aminoglycoside antibiotic-associated nephrotoxicity has been reported to occur in between 10% and 25% of patients receiving a therapeutic course. Critically ill patients appear to have a higher risk for nephrotoxicity with reported rates as high as 58%. The large variance is in part a result of the use of different definitions of toxicity, variability between agents in the class, and the risk factors present in the study population.

Clinical Presentation Clinical evidence of aminoglycoside-associated nephrotoxicity is typically seen within 5 to 10 days after initiation of therapy and manifests as a gradual progressive rise in $S_e$ and BUN and decrease in creatinine clearance. Patients usually present with nonoliguria, i.e., they maintain urine volumes greater than 500 mL/day and sometimes have microscopic hematuria and proteinuria. Although renal magnesium wasting can occur (i.e., daily excretion of more than 10 to 30 mg), the risk of symptomatic hypomagnesemia is generally low. Full recovery of renal function is common if aminoglycoside therapy is discontinued immediately upon discovering signs of toxicity. However, severe AKI may develop occasionally, and for these individuals renal replacement therapy may be required (see Chap. 51). The diagnosis of aminoglycoside-associated nephrotoxicity is often difficult, particularly in critically ill patients with multiple comorbidities and is confounded by other factors that are independently associated with the development of AKI. For instance, concurrent dehydration, sepsis, hypotension, ischemia, and use of other nephrotoxic drugs frequently contribute to AKI in patients who are receiving aminoglycosides.

Pathogenesis Aminoglycoside-associated ATN is primarily due to accumulation of high drug concentrations within proximal tubular epithelial cells, and subsequent generation of reactive oxygen species that produce mitochondrial injury, which leads to cellular apoptosis and necrosis. This results in cell sloughing from proximal tubular basement membranes into the tubular lumen, which can result in tubular obstruction and back leakage of the glomerular filtrate across the damaged tubular epithelium. Toxicity is related to cationic charge of the drugs in this class, which facilitates their binding to negatively charged renal tubular epithelial membrane phospholipids in the proximal tubules, followed by intracellular transport and concentration in lysosomes. The number of cationic groups on the drug molecule appear to correlate with the degree of nephrotoxicity, which is consistent with the observation of higher rates of toxicity with neomycin versus gentamicin, followed by tobramycin, then amikacin.

Risk Factors Multiple risk factors for aminoglycoside-associated nephrotoxicity have been identified: the aggressiveness of aminoglycoside dosing, synergistic toxicity as the result of combination drug therapy and preexisting clinical conditions of the patient (Table 55–2). Prevention Aminoglycoside-associated ATN may be prevented by careful and cautious selection of patients and the use of alternative antibiotics whenever possible and as soon as microbial sensitivities are known. Commonly used alternatives include fluoroquinolones (e.g., ciprofloxacin or levofloxacin) and third- or fourth-generation cephalosporins (e.g., ceftazidime or cefepime). When aminoglycosides are necessary, gentamicin, tobramycin, and amikacin are most commonly used, but therapy should be selected to optimize antimicrobial efficacy. Furthermore, it is imperative to avoid volume depletion, limit the total aminoglycoside dose administered, and avoid concomitant therapy with other nephrotoxic drugs. Future therapeutic alternatives may include new aminoglycoside congeners that retain the desired bactericidal activity and yet are devoid...
of nephrotoxicity, and may also include concurrent use of antioxidant compounds such as vitamin E and N-acetylcysteine.

Prospective, individualized pharmacokinetic monitoring has been used for more than three decades, and its use has been associated with a decrease in the incidence of aminoglycoside-associated nephrotoxicity. These studies, however, were often small and statistically underpowered. High-dose intermittent dosing of aminoglycosides, termed once daily dosing, used in combination with other antibiotics, has been intensively investigated as a practical cost-effective method to maintain antimicrobial efficacy while reducing AKI. The reduction in incidence may be the result of limited proximal tubular aminoglycoside uptake during the transient, high-peak serum concentrations, and because of the presence of low aminoglycoside concentrations for a greater proportion of the dosing interval which facilitates excretion of the aminoglycoside. Although greater clinical efficacy and reduced nephrotoxicity may be realized with once daily compared with standard dosing, seriously ill, immunocompromised, and elderly patients, as well as those with preexisting kidney disease, are not ideal candidates for this approach.

Management Aminoglycoside use should be discontinued or the dosage regimen revised if AKI is evident [i.e., there is an $\mathbf{S}$, increase of 0.5 mg/dL (44 $\mu$mol/L) or more that is not attributable to another cause]. Other nephrotoxic drugs should be discontinued if possible, and the patient should be maintained adequately hydrated and hemodynamically stable. Short-term renal replacement therapy may be necessary, but ESRD has rarely been reported to be solely the result of aminoglycoside toxicity.

Radiographic Contrast Media Nephrotoxicity

Incidence The incidence of radiographic contrast media–induced nephrotoxicity (CIN) has declined over the last decade from approximately 15% to 7% of all patients receiving iodinated contrast; yet it remains the third leading cause of hospital-acquired AKI, accounting for up to 11% of cases. The incidence varies depending on the population studied and presence of risk factors; rising from <2% for patients with normal renal function up to 50% for patients with a high risk, such as those with CKD or diabetes mellitus. As the number of risk factors associated with CIN increases, there is a proportional increase in the incidence of nephrotoxicity and in short- and long-term mortality rates. A 5.5-fold increased risk of death has been reported for patients who develop CIN compared with those who do not, with the highest mortality rates observed for patients who develop AKI and require renal replacement therapy. In-hospital and 2-year mortality rates of 36% and 81%, respectively, have been reported for patients who develop CIN and require dialysis; an in-hospital mortality rate of only 7% was observed in those with nephrotoxicity not requiring dialysis.

Clinical Presentation CIN is usually transient in nature, presenting most commonly as nonoliguria with kidney injury apparent within the first 24 to 48 hours after the administration of contrast. The $\mathbf{S}$, concentration usually peaks between 3 and 5 days after exposure, with recovery after 7 to 10 days. However, irreversible oliguric (urine volume <500 mL/day) AKI requiring dialysis has been reported in high-risk patients. Urinalysis typically reveals tubular enzymeuria with hyaline and granular casts but may also be completely void of casts. The urine sodium concentration and fractional excretion of sodium are frequently low, with the latter typically <1% (<0.01).

Pathogenesis The primary mechanisms by which contrast media induce nephrotoxicity are renal ischemia and direct cellular toxicity. Renal ischemia likely results from systemic hypotension and simultaneous acute vasoconstriction caused by disruption of normal prostaglandin synthesis and the release of adenosine, endothelin, and other renal vasoconstrictors. Subsequently, a 50% sustained reduction in renal blood flow that lasts for several hours immediately following contrast administration may be evident. This reduced renal blood flow leads to increased concentrations of contrast in the renal tubules and exacerbates the direct cytotoxicity and ATN. The extent of cellular toxicity is directly related to the duration of tubular cell exposure to contrast. Thus, preservation of high urinary flow rates with adequate hydration before, during, and after contrast administration is vital to keep renal blood flow as high as reasonably possible to minimize tubular cell exposure to the contrast agent. In humans, plasma osmolality is normally between 275 and 290 mOsm/kg (275 and 290 mmol/kg). Since low- and high-osmolar contrast agents are hyperosmolar to plasma [i.e., 600 to 800 mOsm/kg (600 to 800 mmol/kg)] and ~2,000 mOsm/kg (~2,000 mmol/kg), respectively, their use may result in osmotic diuresis, dehydration, renal ischemia, and increased blood viscosity caused by red blood cell aggregation. Oxidative stress has also been implicated in the development of ATN after contrast administration, which may explain the possible benefit of the antioxidant N-acetylcysteine.

Risk Factors Decreased renal blood flow exacerbates the ischemic and direct cytotoxic effects of contrast media on the renal tubules. Therefore, preexisting kidney disease, particularly in those with estimated GFR <60 mL/min/1.73 m² (<0.58 mL/s/m²), is the most important risk factor present in up to 60% of patients who develop CIN. Other patients’ specific risk factors include conditions associated with decreased renal blood flow (i.e., congestive heart failure, dehydration/volume depletion, and hypertension), and patients with atherosclerosis and reduced effective circulating arterial blood volume appear to also have an elevated risk. Diabetes is also a significant risk factor, likely due to coexisting kidney disease (diabetic nephropathy). The presence of multiple myeloma has traditionally been considered a relative contraindication for contrast use, but the risk appears to be associated with concomitant dehydration, kidney

*Strength of recommendations: A, B, and C are good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3 evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

**Prevention**

CIN can be anticipated in the majority of patients who are at risk; so the use of preventative procedures is justified for virtually all patients. Table 55–3 lists the recommended interventions for prevention of contrast nephrotoxicity. All patients scheduled to receive contrast media should be assessed for risk factors, and the risk-to-benefit ratio should be considered. High-risk patients can be identified by evaluating medical history and indication for the contrast study, along with their most recent $S_a$ concentrations. Nephrotoxicity is best prevented in high-risk patients by using alternative imaging procedures (e.g., ultrasound, noncontrast magnetic resonance imaging, and nuclear medicine scans). However, if contrast media must be used, the smallest adequate volume should be administered. If the ratio of the volume of contrast to be infused relative to the patient’s creatinine clearance is ≥3.7 (≥222 if creatinine clearance is expressed in units of milliliters per second), the likelihood of nephrotoxicity is markedly increased. Therefore, in general, the volume of contrast (in milliliters per second) administered should not be greater than twice the baseline estimated creatinine clearance.

Low-osmolar (600 to 800 mOsm/kg; 600 to 800 mmol/kg) nonionic (iohexol and iopamidol) and ionic (ioxaglate) contrast agents may be used to prevent or minimize the incidence of nephrotoxicity. Standard hyperosmolar contrast media (e.g., low- and high-osmolar agent) are not reabsorbed in the kidney and cause osmotic diuresis, which contributes to the renal toxicity observed with these agents. Low-osmolar contrast agents have less than half the osmolality of high-osmolar (~2,000 mOsm/kg; ~2,000 mmol/kg) agents and are associated with less toxicity, especially when used for patients with preexisting kidney disease. However, use of low-osmolar agents does not preclude the development of nephrotoxicity. Even low-osmolar agents are hyperosmolar to plasma, which is likely the reason they are associated with greater nephrotoxicity than the iso-osmolar nonionic contrast agent iodixanol. Iodixanol has been shown to have the lowest risk for CIN for patients with CKD and diabetes.

**CLINICAL CONTROVERSY**

Some clinicians believe that low- or iso-osmolar contrast media should be used for virtually all patients at risk for toxicity. Others believe that the cost-to-benefit ratio of using low-osmolar contrast agents to prevent nephrotoxicity is questionable except for patients at high risk.

Volume expansion and correction of dehydration prior to contrast administration is a mainstay of preventive therapy. Parenteral hydration with isotonic saline before and after contrast administration reduces the incidence of toxicity, particularly in high-risk patients, and is currently the most widely accepted preventative intervention. Volume expansion may exert its beneficial effects through dilution of contrast media, prevention of renal vasoconstriction leading to ischemia, preservation of high urine flow rates, decreased tubular cell exposure to contrast, and avoidance of tubular obstruction. Hydration with isotonic sodium bicarbonate has been shown to provide more protection than saline, perhaps by reducing the formation of pH-dependent oxygen free radicals, but recent studies reported contradictory findings. Larger, adequately powered studies are needed to confirm these findings and to demonstrate conclusively that bicarbonate-based hydration is superior to saline. The use of oral hydration regimens has also been proposed but also requires further study to clarify its role and is not currently recommended in lieu of parenteral hydration.

$N$-acetylcysteine is a thiol-containing antioxidant that may effectively reduce the risk of developing CIN for patients with preexisting kidney disease. Despite the publication of more than 30 clinical trials and 10 metaanalyses, a therapeutic benefit of NAC has not been consistently demonstrated, and its therapeutic role remains controversial. Nevertheless, its use should be considered, along with hydration, for all patients who are at high risk of toxicity. The recommended $N$-acetylcysteine dosing regimen for prevention of CIN is to give four doses of 600 mg to 1,200 mg orally every 12 hours, with the first dose administered prior to contrast exposure (see Table 55–3). Finally, other nephrotoxic drugs should be discontinued if possible, and subsequent contrast studies appropriately timed to minimize cumulative toxicity.
Some clinicians believe that insufficient evidence exists to justify use of N-acetylcysteine for the prevention of contrast-induced nephrotoxicity, while others feel that its safety profile, ease of use, low cost, and potential for benefit are adequate justification for use for all patients.

Continuous venovenous hemofiltration (CVVH) may also be an effective means of preventing CIN. However, because of the logistical issues (e.g., technical difficulty) and high cost of CVVH, currently this approach is not widely used and should be considered only for the highest risk patients in whom contrast exposure is unavoidable. Use of mannitol and furosemide for prevention may be harmful, and recent evidence indicates that fenoldopam, dopamine, and calcium channel blockers are ineffective in the prevention of CIN in CKD patients. Consequently, these approaches are generally not recommended for the prevention of CIN.

Management
Currently there is no specific therapy available for managing established CIN. Care is supportive as described in Chap. 51. Renal function (e.g., Sₐ, urine output), electrolytes (e.g., sodium, potassium), and volume status should be closely monitored, and renal replacement therapy should be used as needed for patients when indicated (see Chap. 51).

Cisplatin Nephrotoxicity
Incidence
Cisplatin is one of the most important and widely used antineoplastic drugs for the treatment of solid tumors, often demonstrating exceptional efficacy (i.e., cure rates over 90% in testicular cancers). Unfortunately, the primary dose-limiting toxicity of platin-containing compounds is nephrotoxicity. The incidence of cisplatin nephrotoxicity was extremely high early in its development, with more than 70% of patients developing AKI in the 1980s. Current estimates are much lower, primarily the result of limiting the total drug dose, reducing the rate of administration, and aggressively hydrating patients, yet it still occurs in 20% to 30% of patients and remains a significant cause of morbidity. Carboplatin, a second-generation platinum analog, is associated with a lower incidence of nephrotoxicity than cisplatin and thus is the preferred agent in high-risk patients.

Clinical Presentation
Cisplatin administration results in impaired tubular reabsorption and decreased urine concentration ability, leading to increased excretion of salt and water (i.e., polyuria) within 24 hours of treatment. Polyuria persists, and a decrease in GFR evidenced by a rise in Sₐ concentration may be seen within 72 to 96 hours after cisplatin administration. Serum creatinine peaks approximately 10 to 14 days after initiation of therapy, with recovery by 21 days. As many as 25% of patients may have reversible elevations in Sₐ and BUN for 2 weeks after cisplatin treatment. However, kidney damage is dose related and cumulative with subsequent cycles of therapy, so the Sₐ concentration may continue to rise, and irreversible kidney injury may result. Hypomagnesemia is a hallmark finding of cisplatin nephrotoxicity, due to impaired magnesium reabsorption and thus increased urinary losses. Hypomagnesemia is often accompanied by hypocalcemia and hypokalemia and may be severe, leading to seizures, neuromuscular irritability, or personality changes. Urinalysis typically reveals leukocytes, renal tubular epithelial cells, and granular casts.

Pathogenesis
The pathogenesis of cisplatin nephrotoxicity is multifactorial in nature and likely begins with cellular uptake and accumulation of the drug in proximal tubular epithelial cells to concentrations that may reach five times the serum concentration. Tubular cell exposure to cisplatin then activates a series of cell signaling pathways, including the mitogen-activated protein kinase (MAPK) pathway, p53, caspase, and the generation of reactive oxygen species, that collectively promote tubular cell injury and death via necrosis and/or apoptosis. Simultaneous production of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) within tubular cells activates an inflammatory response which may worsen the renal insult. Although tubular damage is evident in both the proximal and distal segments, the majority occurs in the proximal tubules and is followed by a progressive loss of glomerular filtration capacity and impaired distal tubular function. Renal biopsies generally reveal necrosis of proximal and distal tubules and collecting ducts, with no obvious morphological changes to the glomeruli.

Risk Factors
Risk factors include increased age, dehydration, renal irradiation, concurrent use of nephrotoxic drugs, large cumulative doses, and alcohol abuse.

Prevention
The best renoprotective strategy during cisplatin treatment incorporates a combination of interventions, including prospective dose reduction and decreased frequency of administration, which usually requires using the platin compounds in combination with other chemotherapeutic agents, avoiding concurrent use of other nephrotoxic drugs, and ensuring patients are euolemic or somewhat hypervolemic prior to initiating treatment. Vigorous hydration with isotonic saline should be used for all patients with a goal of maintaining at least 100 to 150 mL/h of urine output during and after cisplatin treatment. Hydration should be initiated 12 to 24 hours prior to and continued for 2 to 3 days after cisplatin administration at rates of 100 to 250 mL/h, as tolerated, to maintain a urine flow of 3 to 4 L/day. Concurrent use of diuretics such as furosemide and mannitol to maintain urine flow has not been consistently demonstrated to be renoprotective; thus, their use is no longer recommended.

Amifostine, an organic thioephosphate that is converted to an active metabolite, chelates cisplatin in normal cells and reduces the nephrotoxicity, neurotoxicity, ototoxicity, and myelosuppression associated with cisplatin and carboplatin therapy. It is also thought to serve as a thiol donor, thereby reducing intracellular reactive oxygen species and corresponding oxidative stress that plays a critical role in the development of cellular injury. Pretreatment with amifostine should be considered for patients who are at high risk for kidney injury, particularly patients who are elderly, volume depleted, have CKD, or are receiving other nephrotoxic drugs concurrently. The current recommended dose of amifostine is 910 mg/m² administered intravenously over 15 minutes, beginning 30 minutes prior to cisplatin administration. Common toxicities include acute hypotension, nausea, and fatigue.

Promising investigational techniques include the use of hyper-tonic saline (e.g., administration of each dose in 250 mL of 3% saline) to reduce tubular cisplatin uptake, N-acetylcysteine to reduce oxidative damage by acting as a sulphydryl donor, and disulfiram metabolite diethylthiocarbamate to reduce cytchrome P450 2E1-mediated generation of hydroxyl radicals. Recently, the protective effect of melatonin and the ability of cisplatin-incorporated polymeric micelles to maintain antitumor activity while reducing nephrotoxicity were demonstrated. Finally, reduced renal exposure can be achieved with the use of localized intraperitoneal administration in conjunction with systemic administration of sodium thiosulfate for those with peritoneal tumors.

Management
AKI caused by cisplatin therapy is usually partially reversible with time and supportive care, including dialysis. Renal function indices should be closely followed, with Sₐ and BUN concentrations checked daily. Serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed. Hypocalcemia and hypokalemia may be difficult to
reverse until hypomagnesemia is corrected. Progressive kidney disease caused by cumulative nephrotoxicity may be irreversible and in some cases may lead to ESRD and require chronic dialysis support.

**Amphotericin B Nephrotoxicity**

**Incidence** Variable rates of amphotericin B nephrotoxicity have been reported that correspond in large part to the cumulative dose administered. Nephrotoxicity may be seen in nearly 30% of patients receiving median cumulative doses as low as 240 mg and reaches an incidence of >80% when cumulative doses approach 5 g. Although numerous studies demonstrate lower rates of nephrotoxicity with liposomal formulations compared with conventional amphotericin B, it is difficult to compare rates of toxicity between products and studies because of the variability in the study populations, doses administered, and inconsistent definitions of nephrotoxicity and methods of assessment.

**Clinical Presentation** Dose-dependent nephrotoxicity is often evident after administration of cumulative doses of 2 to 3 g as non-liguric, renal tubular potassium, sodium, and magnesium wasting, impaired urinary concentrating ability, and distal renal tubular acidosis. Although the cumulative dose is a significant risk factor, the time to onset of kidney injury varies considerably, ranging from a few days to weeks. Tubular dysfunction usually manifests 1 to 2 weeks after treatment is begun, and potassium and magnesium replacement may be necessary. This is typically followed by a decrease in GFR and a rise in S₃ and BUN concentrations. Consequently, renal function indices should be closely followed, with S₃ and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations monitored every other day and corrected as needed.

**Pathogenesis** Amphotericin B nephrotoxicity occurs predominantly via two mechanisms. The first is direct tubular epithelial cell toxicity resulting from interaction of amphotericin B with ergosterol in the cell membrane, leading to increased tubular cell membrane permeability, lipid peroxidation, and eventual necrosis of proximal tubular cells. Tubular injury appears to be exacerbated by ischemic injury, which is a result of a reduction in renal blood flow and GFR due to afferent arteriolar vasoconstriction.

**Risk Factors** Risk factors that impact the likelihood of developing amphotericin B nephrotoxicity include preexisting kidney disease, large individual and cumulative doses, short infusion times, volume depletion, hypokalemia, increased age, and concomitant administration of diuretics and other nephrotoxins (cyclosporine in particular).

**Prevention** Permanent decrements in GFR are best prevented by incorporating a low threshold [i.e., if S₃ reaches 2 mg/dL (177 μmol/L) on 2 consecutive days] for stopping amphotericin B or switching to a liposomal formulation. Several liposomal amphotericin B formulations are now available and should be used in most high-risk patients as they have been reported to reduce nephrotoxicity by enhancing drug delivery to sites of infection and reducing interaction with tubular epithelial cell membranes. Nephrotoxicity can also be minimized by limiting the cumulative dose, increasing the infusion time, ensuring the patient is well hydrated, and avoiding concomitant administration of other nephrotoxins. Administration of 1 L intravenous 0.9% sodium chloride daily during the course of therapy appears to reduce toxicity and a single infusion of saline 10 to 15 mL/kg prior to administration of each dose of amphotericin B are generally recommended. A number of other antifungal agents such as itraconazole, voriconazole, and caspofungin are viable alternatives and are now routinely used in lieu of amphotericin B for patients at high risk of developing nephrotoxicity.

**Management** Amphotericin B nephrotoxicity is best treated by discontinuation of therapy and substitution of alternative antifungal therapy, if possible. Renal tubular dysfunction and glomerular filtration will improve gradually to some degree in most patients, but damage may be irreversible. Renal function indices should be closely followed, with S₃ and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.

**OSMOTIC NEPHROSIS**

The term *sucrose nephrosis* was first used in 1940 to describe renal lesions observed at autopsy in patients who died of severe AKI following parenteral administration of hyperosmolar sucrose. The lesions were characterized by severe swelling and vacuolization of the proximal tubular epithelial cells. Subsequently, the term *osmotic nephrosis* was used to describe the lesion in light of the suspected mechanism, an osmotic gradient between the tubular lumen and epithelial cells. It is now known that several drugs, including mannitol, low-molecular-weight dextran, hydroxyethyl starch, and radiographic contrast media, or drug vehicles, such as sucrose, maltose, and propylene glycol, are associated with osmotic nephrosis, which may rarely lead to ATN and AKI. Since osmotic nephrosis does not necessarily negatively affect proximal tubular function, its presence may often go undetected in patients without overt signs of ATN. This likely contributes to the extremely low incidence of osmotic nephrosis reported for causative agents. Intravenous immunoglobulin solutions containing hyperosmolar sucrose may cause osmotic nephrosis and AKI in 1% to 10% of cases, which is usually reversible shortly after discontinuing therapy. Recently, saline-based intravenous immunoglobulin solutions have also been implicated in the development of osmotic nephrosis. Although intravenous immunoglobulin-induced nephropathy is the modern prototype for osmotic nephrosis, it is understood that the vehicle (i.e., sucrose or maltose) is the culprit and not the immunoglobulins themselves.

The clinical presentation of osmotic nephrosis is often subtle. While tubular proteinuria or vacuolated tubular cells may be observed on urinalysis for patients with AKI, the definitive diagnosis of osmotic nephrosis is only made via a kidney biopsy. Intravenous immunoglobulin-induced AKI typically presents as oliguria after 3 to 4 days of treatment and may persist for up to 2 weeks. Kidney injury occurs via uptake of the offending agent through pinocytosis into proximal tubular epithelial cells, subsequent formation of vacuoles, and accumulation of lysosomes, which collectively results in an oncotic gradient and thus cellular swelling, tubular luminal occlusion, and compromised cellular integrity. Renal replacement therapy may be necessary for up to 40% of patients developing osmotic nephrosis-associated AKI. However, it is usually reversible, with 80% of patients recovering normal renal function following withdrawal of the offending drug.
Risk factors for osmotic nephrosis include excessive doses of offending agents, preexisting kidney disease, ischemia, older age (>65 years), and concomitant use of other nephrotoxins, particularly cyclosporine. Nephrotoxicity may be prevented by limiting the dose, reducing the rate of infusion, and avoiding dehydration and concomitant nephrotoxins.

HEMODYNAMICALLY MEDIATED KIDNEY INJURY

Hemodynamically mediated kidney injury generally refers to any cause of AKI resulting from an acute decrease in intraglomerular pressure, including "prerenal" states leading to reduced effective renal blood flow (e.g., hypovolemia, congestive heart failure) and medications that affect the renin–angiotensin system. The kidneys receive approximately 25% of resting cardiac output, which renders them particularly susceptible to alterations in renal blood flow and enhances their exposure to circulating drugs. Within each nephron, blood flow and pressure are regulated by glomerular afferent and efferent arterioles to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration, and urine output. Afferent and efferent arteriolar vasoconstrictions are primarily mediated by angiotensin II, whereas afferent vasodilation is primarily mediated by prostaglandins (Fig. 55-1). This specialized blood flow is precisely regulated by interrelations between arachidonic acid metabolites, natriuretic factors, nitric oxide, the sympathetic nervous system, the renin–angiotensin system, and the macula densa response to distal tubular solute delivery. Drug-induced causes of hemodynamic kidney injury typically stem from constriction of glomerular afferent arterioles and/or dilation of glomerular efferent arterioles. ACEIs, angiotensin II receptor blockers, and NSAIDs are the agents that have been most commonly implicated.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN II RECEPTOR BLOCKERS

Incidence

The incidence of ACEI- or angiotensin II receptor blocker (ARB)-mediated kidney injury has not been established. Patients with renal artery stenosis, volume depletion, and congestive heart failure and those with preexisting kidney disease, including diabetic nephropathy, are most likely to experience a significant decline in renal function when therapy with one of these agents is initiated. For example, between 20% to 25% of hospitalized patients with congestive heart failure develop AKI after treatment with ACEIs is initiated. The incidence of ACEI induced AKI may be as high as 23% for patients with bilateral renal artery stenosis and up to 38% for patients with unilateral renal artery stenosis.

Clinical Presentation

Therapy with ACEIs and ARBs will acutely reduce GFR; so a moderate rise in \( S_G \) after initiation of therapy should be anticipated. Importantly, a distinction must be made between a potentially detrimental reduction in GFR and a normal, predictable rise in \( S_G \). An increase in \( S_G \) of up to 30% is commonly observed within 3 to 5 days of initiating therapy and is an indication that the drug has begun to exert its desired pharmacologic effect. The \( S_G \) threshold for discontinuation of ACEI or ARB therapy is unclear. However, an increase in \( S_G \) of more than 30% above baseline in the course of 1 to 2 weeks may necessitate discontinuation of the offending drug.

Pathogenesis

The pathogenesis of ACEI- or ARB-mediated kidney injury is the result of disruption of normal autoregulation of intraglomerular capillary hydrostatic pressure. Normally, the kidney attempts to maintain GFR by dilating the afferent arteriole and constricting the efferent arteriole in response to a decrease in renal blood flow. During states of reduced blood flow, the juxtaglomerular apparatus increases renin secretion. Plasma renin converts angiotensinogen to angiotensin I, and ultimately angiotensin II by angiotensin-converting enzyme. Angiotensin II constricts the afferent and efferent arterioles, but has a greater effect on the efferent arterioles, resulting in a net increase in intraglomerular pressure. Additionally, renal prostaglandins, prostaglandin \( E_2 \) in particular, are released and induce a net dilation of the afferent arteriole, thereby improving blood flow into the glomerulus. Together these processes maintain GFR and urine output (Fig. 55-2).

ACEI- or ARB-mediated kidney injury is the result of a decrease in glomerular capillary hydrostatic pressure sufficient to reduce...
glomerular ultrafiltration. When ACEI therapy (e.g., enalapril or ramipril) is initiated, the synthesis of angiotensin II is decreased, thereby preferentially dilating the efferent arteriole. This reduces outflow resistance from the glomerulus and decreases hydrostatic pressure in the glomerular capillaries, which alters Starling forces across the glomerular capillaries to decrease intraglomerular pressure and GFR and then often leads to nephrotoxicity, particularly in the setting of reduced renal blood flow or effective arterial blood volume (Fig. 55–3), that is, prerenal settings in which glomerular afferent arteriolar blood flow is reduced and the efferent arteriole is vasoconstricted to maintain sufficient glomerular capillary hydrostatic pressure for ultrafiltration.

**Risk Factors**

Patients at greatest risk are those dependent on angiotensin II and renal efferent arteriolar constriction to maintain blood pressure and GFR. These include patients with bilateral renal artery stenosis or stenosis in a single kidney (i.e., renal transplant); patients with decreased effective arterial blood volume (i.e., prerenal states), especially those with congestive heart failure, volume depletion from excess diuresis or gastrointestinal fluid loss, hepatic cirrhosis with ascites, and nephrotic syndrome; patients with pre-existing kidney disease; and patients receiving concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation.

**Prevention**

Hemodynamically mediated AKI caused by ACEIs or ARBs is frequently preventable by recognizing the presence of preexisting kidney disease or decreased effective renal blood flow as a result of volume depletion, heart failure, or liver disease. A common strategy for at-risk patients is to initiate therapy with very low doses of a short-acting ACEI (e.g., captopril 6.25 mg to 12.5 mg), then gradually titrate the dose upward and convert to a longer-acting agent after patient tolerance has been demonstrated. Outpatients may be started on low doses of long-acting ACEIs (e.g., enalapril 2.5 mg) with gradual dose titration every 2 to 4 weeks until the maximum dose or desired response is achieved. Renal function indices and serum potassium concentrations must be monitored carefully, daily for hospitalized patients and every 2 to 3 days for outpatients. Monitoring may need to be more frequent during outpatient initiation of ACEI or ARB therapy for patients with preexisting kidney disease, congestive heart failure, or suspected renovascular disease. Use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (e.g., NSAIDs, diuretics) should be discouraged and dehydration avoided.

**Management**

Acute decreases in renal function and the development of hyperkalemia usually resolve over several days after ACEI or ARB therapy is discontinued. Occasionally patients will require management of severe hyperkalemia, as described in detail in chapter 60.

ACEI or ARB therapy may frequently be reinitiated, particularly for patients with congestive heart failure, after intravascular volume depletion has been corrected or diuretic doses reduced. Slight reductions in renal function [maintenance of a Sₖ concentration of 2 to 3 mg/dL (177 to 265 μmol/L)] may be an acceptable tradeoff for hemodynamic improvement in certain patients with severe congestive heart failure or renovascular disease not amenable to revascularization.

**NONSTERoidal ANTIINFLAMMATORY DRUGS AND SELECTive CYClOXYgenase-2 INHIBITORS**

**Incidence**

The overall safety of NSAIDs is evidenced by the nonprescription availability in the United States of several drugs in the class (e.g., ibuprofen, naproxen, ketoprofen). Although potential adverse renal effects from nonprescription NSAIDs had been a concern, conventional nonselective NSAIDs and selective cyclooxygenase-2 (COX-2) inhibitors are unlikely to acutely affect kidney function in the absence of renal ischemia or excess renal vasoconstrictor activity. Nevertheless, given their general safety and widespread availability, NSAIDs are among the most commonly used drugs. More than 30 million people take NSAIDs daily worldwide. Although the incidence of NSAID-induced AKI is unclear, historical reports suggest that 500,000 to 2.5 million people develop some degree of NSAID nephrotoxicity in the United States annually.

**Clinical Presentation**

NSAID- and COX-2-induced AKI can occur within days of initiating therapy, particularly with a short-acting agent such as ibuprofen, or within days of some other precipitating event (e.g., intravascular volume depletion). Patients typically present with complaints of diminished urine output, weight gain, and/or edema. Urine sodium concentrations [<20 mEq/L (<20 mmol/L)] and fractional excretion of sodium [<1% (0.01)] are usually low, and BUN, Sₖ, potassium, and blood pressure are typically elevated. The urine sediment is usually bland and unchanged from baseline but may show occasional granular casts.

**Pathogenesis**

The pathogenesis of NSAID- and COX-2-induced AKI lies in the disruption of normal intraglomerular autoregulation. Specifically, NSAIDs inhibit cyclooxygenase (COX)-catalyzed synthesis of vasodilatory prostaglandins, including prostaglandins I₂ (prostacyclin) and Eₓ, from arachidonic acid. These prostaglandins are synthesized in the renal cortex and medulla by vascular endothelial and glomerular mesangial cells, and their effects are primarily local and result in net afferent arteriolar vasodilation. Vasodilatory prostaglandins have limited activity in states of normal renal blood flow, but in states of decreased renal blood flow their synthesis is increased and they serve a vital autoregulatory role in the protection against renal ischemia and hypoxia by antagonizing renal arteriolar vasoconstriction due to angiotensin...
II, norepinephrine, endothelin, and vasopressin. Thus, administration of NSAIDs in the setting of reduced renal blood flow will blunt the usual compensatory increase in prostaglandin activity, altering the normal autoregulatory balance in favor of renal vasconstrictors, thereby promoting renal ischemia and a reduction in glomerular filtration.

**Risk Factors**

Risk factors for NSAID- and COX-2-induced AKI include age >60 years, preexisting kidney disease, hepatic disease with ascites, congestive heart failure, intravascular volume depletion/dehydration, concurrent diuretic therapy, or systemic lupus erythematosus. The elderly are at higher risk because of multiple comorbidities, multiple-drug therapies, and reduced renal hemodynamics. Combined use of NSAIDs or COX-2 inhibitors and concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation should be avoided in high-risk patients.

**Prevention**

NSAID- and COX-2 inhibitor-induced AKI can be prevented by recognizing high-risk patients, avoiding potent compounds such as indomethacin and using analogues with less prostaglandin inhibition, such as acetaminophen, nonacetylated salicylates, aspirin, and possibly nabumetone. Nonnarcotic analogues (e.g., tramadol) may also be useful but do not provide antiinflammatory activity. When NSAID therapy is essential for high-risk patients, the minimal effective dose should be used for the shortest duration possible, and NSAIDs with short half-lives should be considered (e.g., sulindac) along with optimal management of predisposing medical problems and frequent renal function monitoring. Moreover, use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (e.g., ACEIs, ARBs, diuretics) should be discouraged in high-risk patients and dehydration avoided.

Traditional, nonselective NSAIDs inhibit COX-1 and COX-2, whereas the selective drugs meloxicam, celecoxib, and valdecoxib preferentially inhibit COX-2. COX-2 inhibitors were anticipated to be beneficial in high-risk patients. However, recent data indicate that they affect renal function similarly to nonselective NSAIDs, and thus caution is warranted with their use, particularly in high-risk patients.

**Management**

NSAID-induced AKI is treated by discontinuation of therapy and supportive care. Kidney injury is rarely severe, and recovery is usually rapid. Occasionally, the hemodynamic insult is sufficiently severe to cause ATN, which can prolong injury.

**CYCLOSPORINE AND TACROLIMUS**

The calcineurin inhibitors cyclosporine and tacrolimus have dramatically enhanced the success of solid-organ transplantation. As many as 94% of kidney transplant patients are prescribed a calcineurin inhibitor-based immunosuppressive regimen. Nephrotoxicity, however, remains a major dose-limiting adverse effect of both drugs. Although delayed chronic interstitial nephritis has also been reported, acute hemodynamically mediated kidney injury is an important mechanism of calcineurin inhibitor-induced nephrotoxicity.

**Incidence**

Historically, reversible AKI occurred frequently in transplant recipients during the first 6 months of cyclosporine therapy. The 5-year risk of CKD after transplantation of a nonrenal organ ranges from 7% to 21%, depending on the type of organ transplanted, and the occurrence of CKD in these patients is associated with more than a fourfold increase in the risk of death.

**Clinical Presentation**

The clinical presentation of acute nephrotoxicity associated with calcineurin inhibitors (i.e., hemodynamically mediated AKI) is quite different from the presentation of chronic nephrotoxicity (see Chronic Interstitial Nephritis below). AKI may occur within days of initiating therapy, manifesting as a rise in SCr concentration and a corresponding decline in creatinine clearance. Hypertension, hyperkalemia, sodium retention, oliguria, renal tubular acidosis, and hypomagnesemia are frequently observed in the absence of urine sediment abnormalities or morphologic lesions. On the other hand, renal biopsy may reveal thickening of arterioles, mild focal glomerular sclerosis, proximal tubular epithelial cell vacuolization and atrophy, and interstitial fibrosis. Biopsy is most useful to distinguish acute calcineurin inhibitor nephrotoxicity from acute cellular rejection of the transplanted kidney, the latter being evidenced by interstitial infiltrates composed of activated lymphocytes (see Chap. 98).

**Pathogenesis**

The acute hemodynamic changes associated with calcineurin inhibitor nephrotoxicity result from an increase in potent vasoconstrictors including thromboxane A2 and endothelin, activation of the renin–angiotensin and sympathetic nervous systems, as well as a reduction in the vasodilators nitric oxide, prostacyclin, and prostaglandin E2. The net effect is an imbalance in afferent and efferent tone, resulting in predominantly afferent vasoconstriction with reduced renal plasma flow and GFR. The mechanism of acute nephrotoxicity is generally thought to be dose related, since renal function improves rapidly following dose reduction.

**Risk Factors**

Risk factors include age over 65, higher dose, concomitant therapy with nephrotoxic drugs (particularly NSAIDs), and interacting drugs that inhibit calcineurin inhibitor metabolism and transport and thus increase systemic exposure, older kidney allograft age, salt depletion, diuretic use, and polymorphic expression of P-glycoprotein. The incidence of AKI with potential progression to chronic nephropathy has decreased since the introduction of lower-dose-therapy regimens. Unfortunately, there has been no apparent reduction in the incidence of the slow, dose-dependent decline in glomerular filtration.

**Prevention**

Because acute hemodynamically mediated kidney injury secondary to cyclosporine and tacrolimus appears to be concentration related, pharmacokinetic and pharmacodynamic monitoring is an important means of preventing toxicity. However, the persistent presence of therapeutic or low cyclosporine concentrations does not totally preclude the development of nephrotoxicity. Calcium channel blockers may antagonize the vasoconstrictor effect of cyclosporine by dilating glomerular afferent arterioles and preventing acute decreases in renal blood flow and glomerular filtration. Lastly, decreased doses of cyclosporine or tacrolimus, primarily when used in combination with other nonnephrotoxic immunosuppressants, may minimize the risk of toxicity, but this may increase the risk of chronic rejection.

**Management**

AKI usually improves with dose reduction and treatment of contributing illness or the discontinuation of interacting drugs.
CKD is usually irreversible, but progressive toxicity may be limited by discontinuation of cyclosporine (or tacrolimus) therapy or dose reduction, with the continuation of other immunosuppressants.82,84 S<sub>e</sub> and BUN should be closely monitored (daily if possible), as should cyclosporine or tacrolimus concentrations, to ensure that serum concentrations are within the narrow therapeutic range.

**CRYSTAL NEPHROPATHY**

Crystal nephropathy is caused by precipitation of drug crystals in distal tubular lumens, which commonly leads to intratubular obstruction, interstitial nephritis, and occasionally superimposed ATN. Nephrolithiasis is a type of crystal nephropathy that results from abnormal crystal precipitation in the renal collecting system, potentially causing urinary tract obstruction with kidney injury. Numerous medications have been associated with development of crystal nephropathy (Table 55–4).

**INTRATUBULAR OBSTRUCTION**

Drugs may induce crystal nephropathy with subsequent intratubular obstruction and AKI by direct (precipitation of the drug itself) and indirect means (i.e., promoting release and precipitation of tissue-degradation products). Antineoplastic drugs may cause acute renal tubular obstruction indirectly by inducing tumor lysis syndrome, hyperuricemia, and intratubular precipitation of uric acid crystals.85 Acute oliguric or anuric kidney injury develops rapidly.

The diagnosis is supported by a urine uric acid-to-creatinine ratio greater than 1. Uric acid precipitation can be prevented by vigorous pretreatment hydration with normal saline, beginning at least 48 hours prior to chemotherapy, to maintain urine output 100 mL/h in adults, administration of allopurinol 100 mg/m<sup>2</sup> thrice daily (maximum of 800 mg/day) started 2 to 3 days prior to chemotherapy, and urinary alkalization to pH 7.0.86

Drug-induced rhabdomyolysis is another form of indirect toxicity, which can lead to intratubular precipitation of myoglobin and, if severe, AKI.87 The most common cause of drug-induced rhabdomyolysis is direct myotoxicity from 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors or statins, including lovastatin and simvastatin. The risk of rhabdomyolysis is increased when these drugs are administered concurrently with gemfibrozil, niacin, or inhibitors of the CYP3A4 metabolic pathway (e.g., erythromycin and itraconazole).88

Intratubular precipitation of drugs or their metabolites can also directly cause AKI. Precipitation of drug crystals is due primarily to supersaturation of a low urine volume with the offending drug or relative insolubility of the drug in either alkaline or acidic urine.89 Volume depletion is an important risk factor for the development of AKI. Urine pH decreases to approximately 4.5 during maximal stimulation of renal tubular hydrogen ion secretion. Certain solutes can precipitate and obstruct the tubular lumen at this acid pH, particularly when urine is concentrated, such as for patients with volume depletion. For example, several antiviral drugs have been associated with intratubular precipitation and AKI.19,90,91 Acyclovir is relatively insoluble at physiologic urine pH and is associated with intratubular precipitation in dehydrated oliguric patients.19,90 Foscarnet complexation with ionized calcium may result in precipitation of calcium-foscarnet salt crystals in renal glomeruli, causing primarily a crystalline glomerulonephritis. The salt crystals may then secondarily precipitate in the renal tubules causing tubular necrosis. The protease inhibitor indinavir has been associated with crystalluria, crystal nephropathy, dysuria, urinary frequency, back and flank pain, or nephrolithiasis in approximately 8% of treated patients.95,96 Intratubular indinavir crystal precipitation can be prevented in nearly 75% of treated patients if one ensures that the patient consumes at least 2 to 3 L of fluid per day.97 Sulfadiazine, when used at high doses, and methotrexate may also precipitate in acidic urine and can cause oligoanuric kidney injury.98 Massive administration of ascorbic acid can also result in obstruction of renal tubules with calcium oxalate crystals. Oxalate, a poorly soluble ascorbic acid metabolite, can also precipitate and worsen renal function when ascorbic acid is administered to patients with AKI, congenital nephroptic syndrome, and renal transplant patients.99,100 Triamterene and the quinolone antibiotic ciprofloxacin may also precipitate in renal tubules and cause kidney injury.99

Kidney injury caused by intratubular precipitation of most tissue-degradation products or drugs and their metabolites can be largely prevented and possibly treated by administering the drug after vigorously prehydrating the patient, maintaining a high urine volume, and urinary alkalization.99

**NEPHROCALCINOSIS**

Nephrocalcinosis is a clinical–pathologic condition characterized by extensive tubulointerstitial precipitation and deposition of calcium phosphate crystals leading to marked tubular calcification.93–95 It is most commonly seen in clinical conditions associated with hypercalcemia and hypercalciuria, such as hyperparathyroidism, malignancy, and less frequently increased intake of calcium or vitamin D. However, nephrocalcinosis can also result from hyperphosphatemia and hyperphosphaturia in the absence of hypercalcemia,
as is known to occur for patients who have received oral sodium phosphate solution (OSPS) as a bowel preparation.28,96

Acute Phosphate Nephropathy
The term acute phosphate nephropathy was coined specifically to describe OSPS-induced nephrocalcinosis, as its pathogenesis is the result of increased phosphate intake rather than hypercalcemia.85 During the last decade, several cases of nephrocalcinosis have been reported after use of OSPS for bowel preparation prior to gastrointestinal procedures,24,39,47–50 and strong associations have recently been demonstrated between exposure to OSPS and a decline in kidney function, particularly in the elderly and those with preexisting kidney disease.100–102 The incidence of acute phosphate nephropathy is between 1 in 1,000 and 1 in 5,000 exposures, translating to roughly 1,400 to 7,000 new cases annually.96 Patients usually present with AKI several days to months after exposure to OSPS. Patients in one cohort of 21 cases of acute phosphate nephropathy presented with AKI and a mean $S_p$ of 3.9 mg/dL (345 μmol/L) at a median of 1 month after colonoscopy.95 Low-grade proteinuria (<1.0 g/day), normocalcemia, and bland urinary sediment are usually observed. Extensive deposition of calcium phosphate in the distal tubules and collecting ducts without glomerular or vascular injury is the hallmark of acute phosphate nephropathy.93,95 Risk factors include advanced age, preexisting kidney disease, female sex, hypertension, diabetes, bowel conditions associated with prolonged intestinal transit, high sodium phosphate dosage, volume depletion, and medications that affect renal perfusion or function (e.g., diuretics, lithium, NSAIDs, ACEIs, or ARBs).96

Nephrolithiasis
Nephrolithiasis (formation of renal calculi or kidney stones) does not present as classic nephrotoxicity since GFR is usually not decreased. Drug-induced nephrolithiasis can be the result of abnormal crystal precipitation in the renal collecting system, potentially causing pain, hematuria, infection, or, occasionally, urinary tract obstruction with kidney injury. The overall prevalence of drug-induced nephrolithiasis is estimated to be 1%.103

Kidney stone formation, possibly also accompanied by intratubular precipitation of crystalline material, has been a rare complication of drug therapy. Until the acquired immune deficiency syndrome (AIDS) era, triamterene had been the drug most frequently associated with kidney stone formation, with a prevalence of 0.4%.104 Sulfa diazine is a poorly soluble sulfonamide that has caused symptomatic acetylsulfadiazine crystalluria with stone formation and flank or back pain, hematuria, or kidney injury in up to 29% of patients treated with the drug.96 A high urine volume and urinary alkalization to pH >7.15 may be protective. Numerous other drugs have been implicated in the development of nephrolithiasis, including the antiviral drugs nefinavir and foscarnet, the antibacterial agents ciprofloxacin, amoxicillin, and nitrofurantoin, and various products containing cepheide, norephedrine, and pseudoephedrine.103 Most recently, a catastrophic outbreak of nephrolithiasis occurred in China stemming from consumption of melamine-contaminated dairy products. Most of those affected were children younger than 3 years of age. The now classic presentation consisted of dysuria, hematuria, occasional proteinuria, and stone passage: AKI occurred in 2.5% of the cases.104

GLOMERULAR DISEASE
Proteinuria, particularly nephrotic range proteinuria (defined as urine protein excretion greater than 3.5 g/day per 1.73 m²) with or without a decline in the GFR is a hallmark sign of glomerular injury (see Chap. 56).105 Several different glomerular lesions may occur, including minimal change disease, focal segmental glomerulosclerosis, and membranous nephropathy, mostly by immune mechanisms rather than direct cellular toxicity. Although drug-induced glomerular disease is uncommon, a variety of agents have been implicated.106

Minimal Change Glomerular Disease
Drug-induced minimal change glomerular disease is frequently accompanied by interstitial nephritis and is most common during NSAID therapy.107 Lithium, quinolone antibiotics, and interferon-α have also been implicated.108 Patients present abruptly with nephrotic range proteinuria, hypoalbuminemia, and hyperlipidemia and rarely with hematuria and hypertension.85,107 The pathogenesis is unknown, but nephrotic range proteinuria as a consequence of NSAID therapy is frequently associated with a T-lymphocytic interstitial infiltrate, suggesting disordered cell-mediated immunity. Proteinuria usually resolves rapidly after discontinuation of the offending drug, and a 3- to 4-week course of corticosteroids may help resolve the lesion. More than 90% of adults achieve complete remission over the course of several months.105

Focal Segmental Glomerulosclerosis
Focal segmental glomerulosclerosis (FSGS) is characterized by patchy areas (i.e., only some glomeruli are partially affected by the disease) of glomerular sclerosis with interstitial inflammation and fibrosis (see Chap. 56). FSGS is becoming the most common cause of nephrotic syndrome in African Americans and whites in the United States.108 It represents a pattern of glomerular injury, not a disease per se, and is the final common pathway by which normal glomerular components are replaced by fibrous scar tissue. FSGS has been described in the setting of chronic heroin abuse (known as heroin nephropathy).109 The pathogenesis is unknown but may include direct toxicity by heroin or adulterants and injury from bacterial or viral infections accompanying intravenous drug use. The bisphosphonates pamidronate and zoledronate, commonly used to treat osteoporosis, malignancy-associated hypercalcemia, and Paget disease, are associated with the development of a particularly aggressive variant of FSGS called collapsing glomerulopathy.108 It presents with massive proteinuria (>8 g/day), and it is typically characterized by rising $S_p$ at diagnosis and rapid progression to ESRD.109,110 Patients receiving intravenous formulations, high doses, or prolonged therapy are at highest risk.108

Membranous Nephropathy
Membranous nephropathy is characterized by subepithelial immune complex formation along glomerular capillary loops and, although rarely seen, has classically been associated with gold therapy, penicillamine, captopril, and NSAID use.23,108 Patients present with nephrotic range proteinuria and microscopic hematuria, with hypertension and elevated $S_p$ apparent for patients with more advanced disease.106 The pathogenesis may involve damage to proximal tubule epithelium with antigen release, antibody formation, and glomerular immune complex deposition. Proteinuria usually resolves slowly after discontinuing the offending drug. Patients who remain nephrotic after 6 months should be treated with a 6 to 12 month course of immunosuppressive therapy, which typically consists of prednisone and cyclophosphamide.107

TUBULOINTERSTITIAL NEPHRITIS
Tubulointerstitial nephritis refers to diseases in which the predominant changes occur in the renal interstitium rather than the tubules. The presentation may be acute and reversible with interstitial
edema, rapid loss of renal function, and systemic symptoms or chronic and irreversible, associated with interstitial fibrosis and minimal to no systemic symptoms.\textsuperscript{21,25}

**ACUTE ALLERGIC INTERSTITIAL NEPHRITIS**

**Incidence**

The incidence of drug-induced acute allergic interstitial nephritis (AIN) is unclear and likely varies with clinical setting. For example, the incidence has been estimated to be 0.7 cases per 100,000 young outpatient men but from 10% to 27% of kidney biopsies performed in hospitalized patients with unexplained AKI demonstrate AIN.\textsuperscript{110-112} Multiple drugs have been implicated in the development of AIN (Table 55–4).\textsuperscript{21,24,25} It usually manifests 2 weeks after exposure to a drug but may occur sooner if the patient was previously sensitized.\textsuperscript{113}

**Clinical Presentation** Although methicillin-induced AIN is the prototype for AIN, it is now recognized that AIN is associated with all \(\beta\)-lactam antibiotics (including cephalosporins) and numerous other antimicrobials. Clinical signs present approximately 14 days after initiation of therapy and include (with their approximate incidence) fever (27% to 80%), maculopapular rash (15% to 25%), eosinophilia (23% to 80%), arthralgia (45%), and oliguria (50%).\textsuperscript{110,111,113} Systemic hypersensitivity findings of the classic triad of fever, rash, and arthralgia, often along with eosinophilia and eosinophiluria, strongly suggest the diagnosis of AIN. However, this constellation of findings is not consistently reliable as one or more are frequently absent; so caution is warranted in basing diagnosis on hypersensitivity findings alone.\textsuperscript{110,112} Eosinophiluria, an important marker of drug-induced AIN, is frequently absent, possibly because of fragility of eosinophils in urine and inadequate laboratory methodology. Anemia, leukocytosis, and elevated immunoglobulin E levels may occur. Tubular dysfunction may be manifested by acidosis, hyperkalemia, salt wasting, and concentrating defects.\textsuperscript{21,111} The clinical presentation of AIN caused by proton pump inhibitors, which has recently been observed, is similar to that of \(\beta\)-lactams.\textsuperscript{114-116}

NSAID-induced AIN has a different clinical presentation than that seen with most other drugs.\textsuperscript{24} Patients are typically over 50 years of age (reflecting NSAID use for degenerative joint disease), the onset is delayed a mean of 6 months from initiation of therapy compared with 2 weeks with \(\beta\)-lactams, and there is a much lower incidence of fever, rash, and eosinophilia, which collectively may be observed in <10% of patients.\textsuperscript{24,110,112} Concomitant nephrotic syndrome (proteinuria >3.5 g/day) occurs in more than 70% of patients. Prompt diagnosis of AIN is important as discontinuation of the offending drug may prevent irreversible renal damage.\textsuperscript{21} Renal biopsy is the most definitive method for diagnosis.

**Pathogenesis** The pathogenesis of the majority of cases of AIN is considered to be an allergic hypersensitivity response. This is supported by the fact that AIN is characterized as a diffuse or focal interstitial infiltrate of lymphocytes, eosinophils, and occasional polymorphonuclear neutrophils.\textsuperscript{21,111} Granulomas and tubular epithelial cell necrosis are relatively common with drug-induced AIN. Occasionally a humoral antibody-mediated mechanism is implicated by the presence of circulating antibody to a drug hapten—tubular basement membrane complex, low serum complement levels, and deposition of immunoglobulin G and complement in the tubular basement membrane.\textsuperscript{21} More commonly, a cell-mediated immune mechanism is suggested by the absence of these findings and the presence of a predominantly T-lymphocyte.\textsuperscript{113}

**Risk Factors** No specific risk factors have been identified because these are idiosyncratic hypersensitivity reactions. Individuals with other drug allergies may have increased risk and warrant close monitoring.

**Prevention** No specific preventive measures are known because of the idiosyncratic nature of these reactions. Patients must be monitored carefully to recognize the signs and symptoms, because promptly discontinuing the offending drug often leads to full recovery.\textsuperscript{21}

**Management** Corticosteroid therapy is beneficial and should be initiated immediately or soon after diagnosis of AIN along with discontinuance of the offending drug to avoid the risk of incomplete recovery of renal function. While various regimens have been used, high-dose oral prednisone 1 mg/kg/day for 8 to 14 weeks with a stepwise taper has been used successfully.\textsuperscript{111,115} Typical renal function indices (e.g., \(S_e\), BUN) and signs and symptoms of AIN should be monitored closely for improvement.

**CHRONIC INTERSTITIAL NEPHRITIS**

Lithium, analgesics, calcineurin inhibitors, aristolochic acid, and only a few other drugs have been reported to cause chronic interstitial nephritis, which is usually a progressive and irreversible lesion.\textsuperscript{1,21}

**Lithium**

**Incidence** The prevalence of non-dialysis-dependent CKD stemming from chronic lithium nephropathy in the general population of patients treated with lithium was recently estimated to be 1.2%.\textsuperscript{117} The prevalence of lithium-induced ESRD among all ESRD patients is between 0.2% and 0.8%.\textsuperscript{117,118} Several renal tubular lesions are associated with lithium therapy: an impaired ability to concentrate urine (nephrogenic diabetes insipidus) is seen in up to 87% of patients with biopsy proven nephropathy,\textsuperscript{113} and incomplete distal renal tubular acidosis is observed in up to 50% of these patients.\textsuperscript{119}

**Clinical Presentation** Lithium-induced nephropathy is typically asymptomatic and develops insidiously during years of therapy. Blood pressure is normal and urinary sediment is bland, making detection difficult until the disease progresses significantly.\textsuperscript{120} It is usually recognized by rising BUN or \(S_e\) concentrations or the onset of hypertension. Polydipsia (excessive thirst) and polyuria (excessive urination) are observed in 40% and 20%, respectively, of patients with nephrogenic diabetes insipidus (see Chap. 58).\textsuperscript{119} Although interstitial fibrosis may be observed as early as 5 years after beginning therapy, lithium-induced CKD usually occurs after 10 to 20 years of lithium treatment.\textsuperscript{120}

**Pathogenesis** The precise mechanism of chronic lithium-induced nephropathy is not well characterized. Impaired ability to concentrate urine is a result of a decrease in collecting duct response to antidiuretic hormone, which may be related to downregulation of aquaporin 2 water channel expression during lithium therapy.\textsuperscript{120} Chronic tubulo-interstitial nephritis attributed to lithium is evidenced most commonly by biopsy findings of interstitial fibrosis, tubular atrophy, and glomerular sclerosis.\textsuperscript{21,118} The pathogenesis may involve cumulative direct lithium toxicity since duration of therapy correlates with the decline in the GFR.

**Risk Factors** It is now established that long-term lithium therapy is associated with nephrotoxicity in the absence of episodes of acute intoxication, and that the duration of therapy is the major determinant of chronic nephrotoxicity.\textsuperscript{118,120} Increased age may also be a risk factor, but daily dose is not.\textsuperscript{120}

**Prevention** Prevention of acute and chronic toxicity includes maintaining lithium concentrations as low as therapeutically possible, avoiding dehydration, and monitoring renal function. It is unknown whether progression to CKD can be prevented by
stopping lithium use when mild kidney injury is first recognized. This poses a dilemma as lithium is highly effective for affective disorders and the risks and potential benefits of discontinuing such a beneficial drug need to be carefully considered.\textsuperscript{120} However, if lithium therapy is continued, renal function must be monitored and therapy discontinued if it continues to decline. Amiloride has been used for prevention and treatment of lithium-induced nephrogenic diabetes insipidus, since it blocks epithelial sodium transport of lithium into the cortical collecting duct in the distal nephron.\textsuperscript{120,121}

**Management** Symptomatic polyuria and polydipsia can be reversed by discontinuation of lithium therapy or ameliorated with amiloride 5 to 10 mg daily during continued lithium therapy (see Chap. 58).\textsuperscript{103,104,112} If polyuria does not resolve within 7 to 10 days of therapy, then the amiloride dose should be increased to 20 mg daily. Progressive chronic interstitial nephritis is treated by discontinuation of lithium therapy, adequate hydration, and avoidance of other nephrotoxic agents. Lithium serum concentrations, as well as renal function indices, including urine output, BUN, and \( S_{\text{cr}} \), should be monitored closely for resolution of signs and symptoms of toxicity.\textsuperscript{120}

**Cyclosporine and Tacrolimus**

Delayed chronic tubulointerstitial nephritis, considered the Achilles’ heel of calcineurin inhibitor based immunosuppressive regimens, has been reported after several months of therapy and can result in irreversible kidney disease.\textsuperscript{62} Toxicity is progressive and usually manifests as a slowly rising \( S_{\text{cr}} \) concentration and decreased creatinine clearance that may not reflect the severity of histopathologic changes. All three compartments of the kidney can be affected, evidenced by typical biopsy findings that include arteriolar hyalinosis, glomerular sclerosis, and a striped pattern of tubulointerstitial fibrosis.\textsuperscript{82,84,113} The pathogenesis appears to involve sustained renal arteriolar endothelial cell injury and increased extracellular matrix synthesis, which ultimately result in chronic ischemia of the tubulointerstitial compartment because of increased release of endothelin-1, decreased production of nitric acid, and upregulation of transforming growth factor-\( \beta \).\textsuperscript{82} Unlike acute nephrotoxicity, chronic toxicity is not dose dependent.

**Aristolochic Acid**

**Incidence** In the early 1990s, a cluster of young women with rapidly progressive kidney disease leading to ESRD were reported in Brussels, Belgium. The patients had strikingly similar pathologic findings of interstitial fibrosis with tubular atrophy on renal biopsy. Further investigation revealed that all the women were patients of the same weight-loss clinic and had received a weight-loss treatment containing Chinese herbs.\textsuperscript{122} Subsequent analysis of the herb-based treatment demonstrated significant amounts of *Aristolochia fangchi* (Guang fang ji), known to contain aristolochic acid, the major alkaloid of the botanical species *Aristolochia*.\textsuperscript{122} Although the true incidence is unknown, approximately 3% to 5% of patients who received the weight-loss regimen developed disease, and numerous additional cases of aristolochic acid nephropathy have been reported worldwide.\textsuperscript{122}

**Clinical Presentation** Patients with aristolochic acid nephropathy typically present with mild to moderate hypertension, mild proteinuria, glucosuria, and moderately elevated \( S_{\text{cr}} \) concentrations.\textsuperscript{122} Anemia and shrunken kidneys are also common on initial presentation. The overwhelming majority of cases reported to date have been in women. The main pathologic lesions observed in the kidneys are interstitial fibrosis with atrophy and destruction of proximal tubules throughout the renal cortex; in general, the glomeruli are not affected. Perhaps the most remarkable feature of aristolochic acid nephropathy is the rate at which it progresses. In most individuals, ESRD requiring dialysis or transplantation develops within 6 to 24 months of exposure. An alarming high prevalence (approximately 40% to 45%) of urothelial transitional cell carcinoma has been observed in Belgian patients who underwent renal transplantation.\textsuperscript{122}

**Pathogenesis** Although the precise mechanism of aristolochic acid nephropathy and urothelial carcinoma has yet to be characterized. The major components of aristolochic acid are metabolized to mutagenic compounds called *aristolactam I* and *aristolactam II*, respectively, which have been demonstrated to form aristolochic acid–DNA adducts in humans. Recent data indicate that these adducts cause direct DNA damage and may lead to proximal tubular atrophy and apoptosis.\textsuperscript{122}

**Prevention** The primary means of preventing aristolochic acid nephropathy appears to be the limitation of exposure to compounds containing aristolochic acids. Several countries, including the United Kingdom, Canada, Australia, and Germany, have banned the use of *Aristolochia*-containing herbs.\textsuperscript{122}

**PAPILLARY NECROSIS**

Papillary necrosis is a form of chronic tubulointerstitial nephritis characterized by necrosis of the renal papillae, the regions of the kidney where the collecting ducts enter the renal pelvis, which leads to progressive kidney disease.\textsuperscript{21,124} Papillary necrosis is associated with diabetes, sickle cell disease, obstruction and infection of the urinary tract, and most commonly analgesic use.\textsuperscript{21,124}

**Analgesic Nephropathy**

**Incidence** Prototypical analgesic nephropathy is characterized by chronic tubulointerstitial nephritis with papillary necrosis.\textsuperscript{21} Chronic excessive consumption of combination analgesics, particularly those containing phenacetin, was believed to be the major cause and led to the removal of phenacetin and phenacetin mixtures from most world markets. However, contemporary analgesics, particularly aspirin, acetaminophen, and NSAIDs, alone or in combination, are also associated with the development of analgesic nephropathy, but there is insufficient causative evidence to definitively link these nonphenacetin-containing analgesics with nephropathy.\textsuperscript{121} The incidence of analgesic nephropathy has declined significantly since removal of phenacetin from many countries, with the prevalence estimated to now be <5% in the United States adult ESRD population.\textsuperscript{124}

**Clinical Presentation** Analgesic nephropathy is a progressive disease that evolves slowly over several years.\textsuperscript{121} It is difficult to recognize in the early stages of the disease because patients are often asymptomatic,\textsuperscript{121} and it may be underdiagnosed as a cause of ESRD. It is seen more commonly in women than men.\textsuperscript{21} Early manifestations are generally nonspecific and may include headache and upper gastrointestinal symptoms; later manifestations include impaired urinary concentrating ability, dysuria, sterile pyuria, microscopic hematuria, mild proteinuria (<1.5 g/day), and lower back pain. As disease progresses, hypertension, atherosclerotic cardiovascular disease, renal calculi, and bladder stones are common, and pylonephritis is a classic finding in advanced analgesic nephropathy.\textsuperscript{132,125} The most sensitive and specific diagnostic criteria include (1) a history of chronic daily habitual analgesic ingestion (daily use for at least 3 to 5 years); (2) intravenous pyelography, renal ultrasound, or renal computed tomography imaging, which reveals decreased renal mass and bumpy renal contours; (3) elevated \( S_{\text{cr}} \), i.e., up to 4 mg/dL (354 \( \mu \text{mol/L} \)); and (4) papillary calcifications.\textsuperscript{123,124}

**Pathogenesis** Analgesic nephropathy originates in the papillary tip as a result of accumulated toxins, drugs and metabolites,
decreased blood flow, and impaired cellular energy production. The metabolism of phenacetin to acetyaminophen, which is then oxidized to toxic free radicals that are concentrated in the papilla, appears to be the initiating factor that causes toxicity by mechanisms analogous to acetyaminophen hepatotoxicity via glutathione depletion.\textsuperscript{21,119} Cortical interstitial nephritis develops secondary to papillary necrosis. Salicylates potentiate these effects by also depleting renal glutathione, and inhibiting prostaglandin-mediated vasodilation, thus further predisposing the renal medulla to ischemic injury.\textsuperscript{21,119}

**Risk Factors** The epidemiology of analgesic use and analgesic nephropathy continues to evolve. The classic concept persists that risk for ESRD increases with cumulative consumption of combination analgesics, phenacetin, or acetyaminophen and aspirin or NSAIDs. Caffeine combined in combination analgesics may increase risk, but the role is not clear.\textsuperscript{123,124} Chronic use of therapeutic doses of NSAIDs alone, but not aspirin or salicylates alone, can cause analgesic nephropathy. High-dose acetyaminophen use alone is associated with an increased risk for ESRD. However, these associations remain inconclusive as a consequence of study design flaws, as acetyaminophen has been the preferentially prescribed analgesic for patients with chronic kidney disease.\textsuperscript{123,124}

**Prevention** Prevention has depended primarily on public health efforts to restrict the sale of phenacetin and combination analgesics. This has effectively reduced analgesic nephropathy in Australia and Europe.\textsuperscript{123} However, risk continues with ongoing availability of nonprescription combination analgesics containing aspirin, acetyaminophen, and caffeine in the United States and throughout the world.

Individuals requiring chronic analgesic therapy may reduce risk by limiting the total dose, avoiding combined use of two or more analgesics, and maintaining good hydration to prevent renal ischemia and decrease the papillary concentration of toxic substances. Acetyaminophen remains the preferred nonopiate analgesic for patients with preexisting kidney disease.

**Management** Treatment of established nephrotoxicity requires cessation of analgesic consumption.\textsuperscript{119} This can prevent progression and may improve renal function. Renal function indices, including urine output, BUN, and S\textsubscript{Cr}, should be monitored every several months. Patients should also be monitored for the development of transitional cell carcinoma of the renal pelvis, calyces, ureters, and bladder, which may present years after analgesic nephropathy is diagnosed.\textsuperscript{21}

### RENAL VASCULITIS, THROMBOSIS, AND CHOLESTEROL EMBOLI

**RENA L VASCULITIS**

Drug-induced renal vascular disease commonly presents as vasculitis, thrombotic microangiopathy, or cholesterol emboli. Vasculitis implies inflammation of the vessel wall, capillaries, or glomeruli and is typically classified according to vessel size (i.e., small, medium, or large vessel vasculitis).\textsuperscript{25} Small vessel vasculitides usually affect multiple organ systems, including the kidneys and lungs, and are associated with nonspecific inflammatory symptoms such as fever, malaise, myalgias, arthralgias, and weight loss.\textsuperscript{108} Numerous drugs are associated with the development of renal vasculitis, including hydralazine, propylthiouracil, allopurinol, phenytoin, sulfasalazine, penicillamine, and minocycline (Table 55–1).\textsuperscript{25,126} Most drug-induced cases of vasculitis, including hydralazine, propylthiouracil, allopurinol, and penicillamine, have been implicated in the development of antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis.\textsuperscript{25,127} Recently, the antitumor necrosis factor-α drug adalimumab was associated with the development of ANCA-associated renal vasculitis.\textsuperscript{126,128} Patients present with hematuria, proteinuria, oliguria, and red cell casts, frequently along with fever, malaise, myalgias, and arthralgias.\textsuperscript{25,125} Treatment typically consists of withdrawing the offending drug and administration of corticosteroids or other immunosuppressive therapy, and usually leads to resolution of symptoms within weeks to months.\textsuperscript{126}

**Thrombotic Microangiopathy**

Thrombotic microangiopathy is characterized clinically by microangiopathic hemolytic anemia, fragmented red cells, and thrombocytopenia and pathologically by vascular endothelial proliferation, endothelial cell swelling, and intraluminal platelet thrombi in the small vessels, particularly affecting the renal and cerebral capillaries and arterioles.\textsuperscript{24,25,129} The absence of inflammation in vessel walls distinguishes thrombotic microangiopathy from vasculitis. Numerous medications, including oral contraceptive agents, cyclosporine, tacrolimus, muromonab-CD3, many cancer chemotherapeutic agents including mitomycin C, cisplatin, and gemcitabine, interferon-α, ticlopidine, clopidogrel, and quinine are associated with the development of thrombotic microangiopathy.\textsuperscript{24,25,129} Recently, bevacizumab, a humanized monoclonal antibody against vascular endothelial growth factor, was reported to cause thrombotic microangiopathy,\textsuperscript{120} and other drugs in the class have also been implicated in vascular adverse reactions.\textsuperscript{131} Patients may present with fever, neurological dysfunction, elevated S\textsubscript{Cr} and BUN, and hypertension, along with microangiopathic hemolytic anemia and thrombocytopenia.\textsuperscript{25} Kidney injury can be severe and irreversible, although corticosteroids, antiplatelet agents, plasma exchange, plasmapheresis, and high-dose intravenous immunoglobulin G have each induced clinical improvement.

**Cholesterol Emboli**

Anticoagulants (particularly warfarin) and thrombolytics (e.g., urokinase, streptokinase, tissue-plasminogen activator) are associated with cholesterol embolization of the kidney.\textsuperscript{1,132} These drugs act to remove or prevent thrombus formation over ulcerative plaques or may induce hemorrhage within clots, thereby causing showers of cholesterol crystals that lodge in small diameter arteries of the kidney (renal arterioles and glomerular capillaries). Cholesterol crystal emboli induce an endothelial inflammatory response, which leads to complete obstruction, ischemia, and necrosis of affected vessels within weeks to months after initiation of therapy.\textsuperscript{133} Purple discoloration of the toes and mottled skin over the legs are important clinical clues. Treatment is supportive in nature, since kidney injury is generally irreversible.

### COSTS OF DRUG-INDUCED KIDNEY DISEASE

The costs of DIKD are not well defined, but recent data indicate that the pharmacoeconomic implications are enormous. An increase in S\textsubscript{Cr} of ≥0.5 mg/dL (44 μmol/L) is independently associated with a 6.5-fold increase in the odds of death, a 3.5-day increase in length of hospital stay, and nearly $7,500 in excess hospital costs even after adjusting for age, sex, and measures of comorbidity.\textsuperscript{7} A recent report indicates that amphotericin B-induced AKI leads to a mean increased length of hospital stay of 8.2 days and adjusted additional costs of $29,823 per patient.\textsuperscript{133} Lastly, the mean additional in-hospital cost for each episode of contrast-induced AKI has been estimated to be $10,345 per case. The major driver of the increased costs associated with contrast-induced AKI was the cost of the
longer initial hospital stay. The increased availability of automated clinical decision support systems and computer-guided medication dosing for hospital inpatients may improve the safety of potentially harmful drugs and minimize the occurrence of nephrotoxicity in this setting, thereby potentially lowering the corresponding economic consequences.

KEY CONCEPTS

1. Glomerulonephritis is a collection of glomerular diseases mediated by different immunologic pathogenic mechanisms, resulting in varied clinical presentation and therapeutic outcomes.

2. The signs and symptoms associated with glomerulonephritis can be nephritic in nature, characterized by inflammatory injury, or nephrotic in nature, characterized by proteinuria.

3. In the absence of specific and effective therapy for many types of glomerulonephritis, supportive treatments for edema, hypertension, hyperlipidemia, and intravascular thrombosis play important roles in reducing the complications associated with the disease.

4. To maximize therapeutic benefits and minimize drug-induced complications, patients have to be monitored closely to assess their therapeutic responses as well as the development of any treatment-induced toxicities.

5. Among all the types of glomerulonephritis, minimal-change nephropathy is most responsive to treatment. Steroids can induce good responses in most patients during initial treatment as well as relapse.

6. Because of the lack of consistently effective treatment for primary focal segmental glomerular sclerosis, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are commonly used for patients with mild disease to control symptoms. Steroids and immunosuppressive agents are reserved for patients with severe disease.

7. The optimal treatment for lupus nephritis depends on the underlying lesion and disease activity, as well as the severity and duration of the clinical presentation.

8. The treatment of poststreptococcal glomerulonephritis is mainly supportive and symptomatic. Antibiotic therapy does not prevent subsequent diseases but may reduce the severity.

The precise pathogenetic mechanisms of many glomerular diseases remain unknown, and the available therapeutic regimens are still far from optimal. This chapter provides an overview of the primary causes of glomerulonephritis with a focus on their etiology, the pathophysiologic mechanisms responsible for glomerular injury, and the clinical presentation of the eight predominant types of glomerulonephritis. Treatment options and monitoring approaches for each of these types of glomerulonephritis are also discussed. Diabetes mellitus is an important secondary cause of glomerular injury, and a thorough discussion of the pathophysiology and management of this condition can be found in Chap. 83.

NORMAL GLOMERULAR ANATOMY AND FUNCTION

The glomerulus, which is enclosed within the Bowman capsule, consists of two important components: the filtration barrier and the mesangium (Fig. 56–1). The capillary wall, which serves as a filtration barrier, consists of three well-defined layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cell layer. The epithelial cells, also known as podocytes, have specialized foot processes embedded in the outer layer of the GBM. It is across this barrier that fluid flows and ultimately becomes the ultrafiltrate. Under normal conditions, the GBM functions as a compact hydrated gel of matrix proteins with a pore-like structure. The mesangium, which consists of mesangial cells embedded in an extracellular matrix, provides support for the glomerular capillaries and also modulates blood flow through the capillaries.

The unique capillary bed of the glomerulus allows small nonprotein plasma constituents up to the size of insulin, which has a molecular weight of 5.2 kDa, to pass freely while excluding macromolecules equal to or larger than albumin, which has a molecular weight of 69 kDa. The ease of passage of solutes through the glomerular membrane is impacted by both the size and charge of the solute. Fixed,
negatively charged sites are found within the glomeruli in all three layers of the capillary wall: the endothelium, the epithelium, and the GBM. The movement of negatively charged molecules is thus restricted more than that of neutral or positively charged molecules. Different glomerular diseases affect this size- and charge-selective barrier to different extents; consequently, glomerulopathies present with varied clinical features and solute-excretion patterns.

Some of the glomerular cells, such as the epithelial cells, have phagocytic function that can remove macromolecules trapped within the filtration barrier. They are also capable of synthesizing the GBM. In contrast, the mesangial cells regulate glomerular hemodynamics in response to angiotensin II and by producing prostaglandins. These cells also synthesize and respond to various cytokines and thus play a key role in immune-mediated glomerular diseases. Resident phagocytes in the mesangium are responsible for moving macromolecules trapped in the basement membrane into the urinary space. They are also involved in the development of both immune and nonimmune glomerular injury.

EPIDEMIOLOGY AND ETIOLOGY

In the United States in 2007, glomerulonephritis was the third most common cause of end-stage renal disease (ESRD), accounting for approximately 15% of all the living ESRD patients. About 7,500 patients (6.8% of all patients) develop stage 5 chronic kidney disease, which is also called end-stage renal disease (ESRD), because of glomerulonephritis each year.¹

Humoral and cellular immunologic mechanisms participate in the pathogenesis of most glomerulonephritides. Abnormalities in coagulation and metabolism, as well as hereditary and vascular diseases, also contribute to glomerular damage. The histopathologic manifestations vary substantially among the different types of glomerulonephritis. An overview of the primary pathogenetic mechanisms is presented in this section, and specific abnormalities for each of the primary types of glomerulonephritis are presented in subsequent sections.

PATHOPHYSIOLOGY

1. The glomerular lesion may be diffuse (involving all glomeruli), focal (involving some but not all glomeruli), or segmental, also known as local (involving part of the individual glomerulus). The pathologic manifestations may also be described as proliferative (overgrowth of epithelium, endothelium, or mesangium), membranous (thickening of GBM), and/or sclerotic.

2. The glomerular capillary wall is particularly susceptible to immune-mediated injury. Antigen and antibody tend to localize in the glomerulus, probably because of its high blood flow and capillary hydrostatic pressure. Parenchymal damage can be induced as a result of humoral- and cell-mediated immune reactions (Table 56-1). Antibodies and sensitized T lymphocytes are the primary mediators of glomerular injury.²⁻³

3. Production of antibodies to endogenous or exogenous antigens that are recognized as foreign by the host is the first step in humoral immunologic damage to the glomerulus. Endogenous antigens may be intrinsic glomerular antigens, such as Heymann antigen on the epithelial cell or Goodpasture antigen on the GBM, or previously sequestered antigens, such as DNA or thyroglobulin. Exogenous antigens are most often viral, bacterial, parasitic, or fungal in origin. Antineutrophil cytoplasmic autoantibodies (ANCAs) (i.e., autoantibodies that react to the cytoplasmic components of neutrophils and monocytes) are found in patients with idiopathic crescentic glomerulonephritis and also in the accompanying vasculitis.

Complexes of antigens and antibodies may be formed in the circulation and then passively entrapped in the glomerular capillary or mesangium. Alternately, experimental antibodies may combine with endogenous glomerular antigens or exogenous antigens entrapped in the glomerulus to form complexes locally, or in situ.¹ The type and extent of glomerular damage are dependent on the location of the immune complex formation and the rate at which it is removed. Impaired removal facilitates the growth of the complex and thus increases the likelihood of glomerular damage.

Subsequent to antigen–antibody formation, a series of biologic events is triggered that ultimately leads to glomerular injury. Noninflammatory lesions can result from the binding of noncomplement-fixing antibody to the glomerular epithelial cell (mechanism 1) or from the activation of the complement system to form the C5b–9 membrane attack complex (mechanism 2).³ Both mechanisms can damage the glomerular epithelial cell and result in capillary wall injury and proteinuria. Inflammatory lesions are induced by glomerular infiltration of circulating inflammatory cells such as neutrophils, monocytes/macrophages, and platelets (mechanism 3) or by proliferation of resident glomerular mesangial cells (mechanism 4), resulting in GBM damage.³

The migration of neutrophils and monocytes to the glomerular tufts is promoted by chemoattractants such as complement fragments (C3a and C5a), platelet-activating factor, interleukin-8, and monocyte chemotactic protein-1.¹ Various cytokines, chemokines, and growth factors are then released to participate in the inflammatory process.²

T cells sensitized to glomerular antigen, macrophages, and resident mesangial cells are important participants in cell-mediated injury. Sensitized T cells can cause glomerular hypercellularity in the absence of antibody deposition.²⁻⁴ Cytotoxic T cells may bind with the target cells and destroy them. Alternatively, a delayed-type hypersensitivity reaction may be initiated by activated T cells through the release of lymphokines to attract, activate, and transform monocytes into macrophages.³ These humoral and cellular mediators, in conjunction with a host of toxic molecular entities including reactive oxygen species, proteinases, eicosanoids, and procoagulants, which are secreted by neutrophils, macrophages, platelets, and resident glomerular cells, can alter the permeability, blood flow, and function of the glomeruli. Vascular constriction and occlusion follow and result in the eventual destruction of the glomeruli.

Acute forms of glomerular injury frequently lead to chronic and persistent renal dysfunction, even though the original immune factors that induced the initial glomerular injury have resolved. Experimental and clinical investigations suggest that a variety of factors may participate in the progression of renal injury. These factors include systemic and glomerular hypertension, high dietary protein intake, proteinuria, glomerular hypertrophy, hyperlipidemia, activation of the coagulation system, abnormalities of calcium and phosphorus balance, and tubulointerstitial injury. The degree of proteinuria not only is an index of the severity of glomerular disease but also has been associated with an increased rate of progression of renal injury. Heavy

proteinuria is an indicator of poor prognosis in various glomerular
diseases.

Proteinuria is also accompanied by an increased flux of
macromolecules across the mesangium. The mesangial over-
load may then lead to structural damage. The passage of serum
components, such as complement, across the GBM may have a
pathophysiologic effect on the glomerular epithelial cells and alter
the integrity of the glomerular filtration barrier. The damaging
effects of macromolecules other than albumin, such as immuno-
globulins, lipoproteins, transferrin, and complement, remain to
be characterized.

### CLINICAL PRESENTATION

Although patients with glomerular disease may present with
an array of signs and symptoms, they are often categorized into
one of two broad classifications: nephritic syndrome or nephrotic
syndrome (Table 56–2). The unique clinical presentation charac-
teristics of the predominant glomerulopathies are described in
the individual disease sections, presented later in the chapter.

Nephritic syndrome reflects glomerular inflammation and fre-
quently results in hematuria. White cells and cellular and granular
casts are commonly found in the urine. In contrast, nephrotic syn-
drome reflects noninflammatory injury to the glomerular structures
and results in few cells or cellular casts in the urine. Initially, there
may be limited or no reduction in renal excretory function.

Hematuria occurs when red blood cells leak through the open-
ings of the GBM. The presence of red cell casts is highly indicative
of glomerulonephritis or vasculitis. The presence of dysmorphic red
blood cells in the urine is suggestive of glomerular disease. The red
blood cells are damaged as they pass through the openings in the
GBM or the cells may sustain osmotic injury as they travel through
the different osmotic environments within the lumen of the kidney
tubules.

The presence of proteinuria indicates a defect of the size- and/or
charge-selective barriers within the GBM. Normal urinary protein
excretion is between 40 and 80 mg/day, with a maximum of 150
mg. Fewer than 20 mg of the excreted proteins are albumin. Most of
the albumin that enters the glomerular filtrate is either reabsorbed
or catabolized by the tubular epithelium. The dipsticks that are
commonly used to identify proteinuria detect only albumin; they
become positive when protein excretion is more than 300 to 500
mg/day. They are therefore unable to detect the early stages of renal
injury secondary to diabetes mellitus or hypertension, which often
result in microalbuminuria with urinary albumin excretion ranges
between 30 and 300 mg/day. Chemstrip Micral-Test II (Roche
Diagnostics, Indianapolis, IN), a simple immunoassay on a dipstick,
permits specific and semiquantitative determination of urinary
albumin concentrations at five levels: 0, 10, 20, 50, and 100 mg/L.
Another qualitative test, Micro-Bumintest (Bayer Diabetes Care,
Mishawaka, IN), registers a positive reading when the urine albu-
mum concentration is greater than 40 mg/L.

Hypertension is common for patients with glomerular diseases,
as a result of renal salt retention causing plasma volume expansion.
In contrast, increased activity of vasoconstrictors such as angio-
tensin II is often the cause for patients with chronic glomerular
diseases. Scarring of the glomerulus resulting in regional ischemia
is thought to be responsible for the hypertension. Activation of the
sympathetic nervous system and the release of vasoconstrictor sub-
stances may also contribute.

### NEPHRITIC SYNDROME

Glomerular bleeding resulting in hematuria is typical in nephritic
syndrome. Dysmorphic red cells, especially acanthocytes, are a
sensitive and specific marker of glomerular bleeding. The presence
of pus and cellular and granular casts in the urine is common. The
extent of proteinuria is variable. Patients with severe nephritic
glomerular injury have renal function impairment because of the
reduced glomerular surface area available for filtration, as a result
of constriction of the capillary lumen by proliferating mesangial cells
or inflammatory cells.

### CLINICAL PRESENTATIONS OF NEPHRITIC
AND NEPHROTIC SYNDROMES

#### General
- The patients are generally not in acute distress

#### Symptoms
- The patients may not experience any major symptoms

#### Nephritic Signs
- Hematuria
- Hypertension and edema as renal function declines

#### Laboratory Tests
- Proteinuria up to 3 g/day
- Pus, cellular and granular casts in urine is common
- Hypoproteinemia
- Hypercoagulable state for some patients

#### Nephrotic Syndrome
- Edema
- Weight gain
- Fatigue
- Proteinuria, >3.5 g/day/1.73 m²
- Hyperlipidemia
- Lipiduria

### NPHRITIC SYNDROME

Nephrotic syndrome is characterized by proteinuria greater than 3.5
g/day per 1.73 m², hypoproteinemia, edema, and hyperlipidemia. A
hypercoagulable state may also be present in some patients. The
syndrome may be the result of primary diseases of the glomerulus,
or be associated with systemic diseases such as diabetes mellitus,
lupus, amyloidosis, and preeclampsia. Hypoproteinemia, especially
hypoalbuminemia, results from increased urinary loss of albumin
and an increased rate of catabolism of filtered albumin by proxim-
tubular cells. The compensatory increase in hepatic synthesis of
albumin is insufficient to replenish the protein loss, probably
because of malnutrition.
Edema formation in patients with nephrotic syndrome was traditionally thought to be driven by the reduced plasma oncotic pressure secondary to hypoalbuminemia. If the oncotic pressure is low, the movement of fluid from the vascular space to the interstitial compartment results in a reduction of the plasma volume, which can trigger compensatory renal sodium and water retention through the activation of the renin–angiotensin–aldosterone axis, vaspressin, and the sympathetic nervous system (the “underfill” mechanism). However, experimental data reveal that the plasma volume is actually normal or elevated. Hypoalbuminemia may not cause edema until the serum albumin concentration is less than 2 g/dL (20 g/L). In addition, the transcapillary oncotic pressure gradient is not as high as previously thought because increased lymphatic flow reduces the interstitial oncotic pressure by removing protein and fluid from the interstitium, thereby reducing the transcapillary oncotic pressure gradient. Instead, fluid retention is likely mediated by a primary increase in sodium reabsorption at the distal nephron, which is probably caused by tubular resistance to the action of atrial natriuretic peptide (the “overflow” mechanism). It is likely that both mechanisms may contribute to nephrotic edema in different patients.

Albuminuria greater than 3 g daily is associated with a significant increase in serum cholesterol concentrations for patients with primary glomerular disease. Hyperlipidemia in nephrotic syndrome is characterized by elevated serum total cholesterol and triglyceride concentrations, with increased very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) cholesterol concentrations. Lipoprotein (a) levels may also be increased. The reduced plasma oncotic pressure as a result of hypoalbuminemia may stimulate hepatic synthesis of lipids and lipoproteins. The increased VLDL production and increased liver cholesterol synthesis, along with a decrease in LDL receptor activity, can then lead to an increase in LDL cholesterol concentrations. In addition, reduced serum albumin or the loss of a liporegulatory substance may result in reduced VLDL clearance.

Nephrotic patients with hyperlipidemia, especially those with concomitant hypertension, are presumed to have an increased risk for atherosclerotic vascular disease. Hyperlipidemia also promotes the progression of glomerular injury, as evidenced by glomerulosclerosis, mesangial expansion, and hyalination. Many patients with nephrotic syndrome have a hypercoagulable state caused by defects of several control proteins in the coagulation cascade. The concentration of the coagulation inhibitor antithrombin III is reduced because of increased loss in the urine. A reduced amount of the coagulation inhibitors proteins C and S, along with increased concentrations of factors V and VIII, increased fibrinogen concentrations and abnormal platelet function, may also contribute to the hypercoagulable state. The net result of these alterations in coagulation is an increased risk for arterial and venous thrombosis, especially in the deep veins and renal veins. As many as 25% of patients with membranous nephropathy may have renal vein thrombosis.

### DIAGNOSIS

Patients with suspected glomerular disease should have an extensive medical history obtained to identify potential systemic causes (Table 56–3). Medication, environmental, and occupational histories may also help identify possible exposure to potentially nephrotoxic agents. A carefully conducted physical examination and laboratory evaluation may reveal the presence of systemic diseases that may contribute to the development of glomerular disease (Fig. 56–2). In addition, the patient’s age, gender, and ethnic background may be helpful in pinpointing the specific type of glomerular disease. Many of the conditions are more prevalent in certain age groups, although they may occur at any age. For example, proliferative glomerulonephritis is more common in those younger than 40 years of age, whereas the incidence of membranous glomerulonephritis is dramatically higher in those older than 50 years of age.

Laboratory evaluation such as urinalysis can help differentiate the nephrotic or nephritic nature of the disease. The glomerular filtration rate (GFR) may be used to determine the extent of glomerular damage. In the early stages of the disease, the GFR may remain normal. Initial injury to the glomerulus primarily lowers the permeability coefficient ($K_f$) of the GBM by reducing the surface area available for filtration and/or the unit permeability of the membrane. The reduced permeability is compensated by an elevation in the glomerular capillary hydrostatic pressure through afferent arteriolar dilation and efferent arteriolar constriction. Extensive glomerular damage may therefore be present before a substantial reduction of total GFR is evident.

Although the cause of glomerular disease may be established from clinical and laboratory evaluation, sometimes percutaneous renal biopsy may be needed to provide a definitive diagnosis.

TREATMENT

Glomerulonephritis

■ GENERAL APPROACH TO TREATMENT

The management of patients with glomerulonephritis involves specific pharmacologic therapy for the glomerular disease and supportive measures to prevent and/or treat the pathophysiologic sequelae, namely, hypertension, edema, and progression of renal disease. For patients with nephrotic syndrome, supportive therapy should also address the management of extrarenal complications of heavy proteinuria, namely, hypoalbuminemia, hyperlipidemia, and thromboembolism. Because patients with significant proteinuria tend to have more rapid decline of renal function, reduction of proteinuria thus becomes critical in delaying the rate of progression toward ESRD.

Immunosuppressive agents, alone or in combination, are commonly used to alter the immune processes that are responsible for the glomerulonephritides. Corticosteroids, in addition to their immunosuppressive effect, also possess antiinflammatory activities. They reduce the production and/or release of many substances that mediate the inflammatory process, such as prostaglandins, leukotrienes, platelet-activating factors, tumor necrosis factors, and interleukin-1 (IL-1). Movement of leukocytes and macrophages to the site of inflammation is also inhibited. The immunosuppressive effects of corticosteroids are mediated through the inhibition of the release of IL-1 and tumor necrosis factor by activated macrophages, and interleukin-2 (IL-2) by activated T cells. In addition, the actions of migration-inhibiting factor and γ-interferon are inhibited. Processing of antigens is thus affected by the presence of corticosteroids. Cytotoxic agents, such as cyclophosphamide, chlorambucil, or azathioprine, are commonly used to treat glomerular diseases. Cyclosporine can reduce lymphokine production by activated T lymphocytes, and it may decrease proteinuria by improving the perselectivity of the GBM. Mycophenolate mofetil is useful in different glomerulonephritides because of its effects on T- and B-cell lymphocytes.

Because many immune factors are implicated in the pathogenesis of glomerulonephritis, plasmapheresis may be used to remove these mediators. During the procedure, whole blood is removed from the body and centrifugation is used to separate the cellular elements from the plasma. The cells are then infused back to the patient after resuspension in saline or plasma substitute. The plasma proteins, presumably including the pathogenic immune factors, are thereby removed from the patient.

Recently, many novel targets were identified and new agents are being evaluated for their usefulness to control the disease, preserve renal function, and improve patient outcome. To stay abreast of the expanding availability of treatment options, one can routinely consult one of the clinical trial registries, such as www.clinicaltrials.gov.10

■ SUPPORTIVE THERAPY

For patients with nephrotic syndrome, dietary measures involve restriction of sodium intake to 50 to 100 mEq/day (50 to 100 mmol/day),11 protein intake of 0.8 to 1 g/day,11,12 and a low-lipid diet of less than 200 mg cholesterol. Total fat should account for less than 30% of daily total calories.13 Sodium restriction is important not only in the control of edema, but also in the control of hypertension and proteinuria. Similarly, protein restriction not only helps to reduce proteinuria but also has a potential role in retarding the progression of renal disease. Patients should also stop smoking because a dose-dependent increase in risk for developing ESRD was observed in men with primary inflammatory (immunoglobulin A glomerulonephritis) or noninflammatory (polycystic kidney disease) renal diseases.15

Edema

Management of nephrotic edema involves salt restriction, bedrest, and use of support stockings and diuretics. However, severe salt restriction is difficult to achieve and prolonged bedrest could predispose nephrotic patients to thromboembolism. Hence the use of a loop diuretic such as furosemide is frequently required. Although the delivery of diuretic to the kidney tubules is normal, the presence of large amounts of protein in the urine promotes drug binding, and thereby reduces the availability of the diuretic to the luminal receptor sites. In addition, reduced sodium delivery to the distal tubule secondary to decreased glomerular perfusion may also alter diuretic effectiveness. Large doses of the loop diuretic, such as 160 to 480 mg of furosemide, may be needed for patients with moderate edema (see Chap. 58). In some instances, a thiazide diuretic or metolazone may be added to enhance natriuresis.11,14 Alternatively, continuous intravenous infusion of a loop diuretic, such as furosemide 160 to 480 mg/day, may be employed.15 For patients with morbid edema, albumin infusion may be used to expand plasma volume and to increase diuretic delivery to the renal tubules, thus enhancing diuretic effect. However, it may precipitate congestive heart failure and may also reduce therapeutic response to steroid in minimal-change nephropathy. For patients with significant edema, the goal of treatment should be a daily loss of 1 to 2 lb (0.45 to 0.9 kg) of fluid until the patient’s desired weight has been obtained.

FIGURE 56-2. Clinical presentations of glomerulonephritis. (AP, anaphylactoid purpura; GBM, glomerular basement membrane; GN, glomerulonephritis; HUS, hemolytic uremic syndrome; IgA, immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.)
Hypertension
Optimal control of hypertension for patients with glomerular disease is important in reducing both the progression of renal disease and the risk for cardiovascular disease (see Chaps. 19 and 52). The target blood pressure for patients with chronic kidney disease defined by GFR <60 mL/min (<1.0 mL/s) or albuminuria >300 mg/day is less than 130/80 mm Hg. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) delay the loss of renal function for patients with diabetic and nondiabetic (primarily glomerulonephritis) renal diseases.12 Nondihydropyridine calcium channel blockers (e.g., diltiazem, verapamil) reduce proteinuria and preserve renal function and could be used as an additional agent. In contrast, the dihydropyridine calcium channel blockers (e.g., nifedipine, amlodipine, or niisoldipine) are effective in lowering blood pressure, but without the benefit of proteinuria reduction.18

Proteinuria
Dietary protein restriction reduces proteinuria and may retard renal function deterioration. Secondary analysis of the Modification of Diet in Renal Disease Study for patients with moderate renal insufficiency [GFR of 25 to 55 mL/min/1.73 m² (0.24 to 0.53 mL/s/m²)] revealed that reduced protein intake (0.66 g/kg/day) delayed the rate of GFR deterioration for patients with severe renal insufficiency [GFR of 13 to 24 mL/min/1.73 m² (0.13 to 0.23 mL/s/m²)].19 Consequently, modest protein restriction of 0.8 g/kg/day is reasonable for patients with moderate renal insufficiency. Decreasing dietary protein also reduces the intake of phosphorus and potassium. In many instances, the potential benefits of protein restriction have to be balanced against the need for protein intake to overcome nutritional deficiencies. For nondialyzed patients who have GFRs of less than 25 mL/min/1.73 m² (0.24 mL/s/m²), dietary protein intake should be reduced to 0.6 g/kg/day.22

It is now recognized that proteinuria is an independent risk factor for renal function decline and cardiovascular disease.20 Reducing proteinuria can retard renal function loss and delay the progression to ESRD.21 The antiproteinuric effect of ACEIs is associated with a fall in filtration fraction, suggesting a reduction in intraglomerular pressure. Recent studies show that ACEIs and ARBs may also have direct effects on podocytes, resulting in reduction of proteinuria and glomerular scarring.22 In addition, angiotensin-converting enzyme (ACE) inhibition may also reduce the effect of angiotensin II on renal cell proliferation, thereby reducing sclerosis. These beneficial effects on proteinuria are beyond what can be attributed by the drug’s antihypertensive effects (see Chap. 52).23,24

Addition, with the blockade of the angiotensin II type 1 receptor, the angiotensin II produced by the non-ACE pathways may still act on the angiotensin II type 2 receptors, further facilitating vasodilation.25 An angiotensin II receptor antagonist should therefore be added to the regimen for those patients who do not attain full and persistent remission of proteinuria with an ACEI alone.

Nonsteroidal antiinflammatory drugs (NSAIDs) probably reduce proteinuria through prostaglandin E₂ inhibition, resulting in a reduction of intraglomerular pressure, a decrease in GFR, and restoration of the barrier size selectivity of the GBM.13 Indomethacin and meclofenamate are the two most evaluated NSAIDs. Their antiproteinuric effect is comparable to that attained with ACEIs, and combined treatment with an ACEI results in additional proteinuria reduction.27 However, adherence to a low-sodium diet or concurrent use of a diuretic is needed to maximize the antiproteinuric effect. Because of their potential for nephrotoxicity, especially for patients with poor renal function, long-term use of an NSAID for renoprotection is not preferred.23

Hyperlipidemia
An abnormal lipoprotein profile increases the risk of atherosclerosis and coronary heart disease for patients with nephrotic syndrome. It is therefore important to treat patients with persistent nephrotic syndrome and sustained dyslipidemia, especially those with high VLDL and LDL cholesterol levels in the presence of a normal or low high-density lipoprotein cholesterol level (see Chaps. 28 and 53). Therapy is especially needed for those with concurrent atherosclerotic cardiovascular disease, or with additional risk factors for atherosclerosis, such as smoking and hypertension.4

A low-fat diet is usually not sufficient to correct hyperlipoproteinemia.11 β-Hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, also known as “statins” such as lovastatin, pravastatin, simvastatin, and fluvastatin, are considered the treatment of choice.31 They reduce total plasma cholesterol concentration, LDL cholesterol, and total plasma triglyceride concentrations.9 Aside from the lipid-lowering effects, statins may confer renoprotection through different mechanisms, including reduction of cell proliferation and mesangial matrix accumulation and antiinflammatory and immunomodulatory effects.28 Recent clinical studies show that they can reduce proteinuria and delay renal function loss.20,30 The combined use of an ACEI with a statin may offer additional benefits in controlling nephrotic hyperlipidemia.19

Anticoagulation
Renal vein thrombosis, pulmonary emboli, or other thromboembolic events, are serious and common complications of nephrotic syndrome, and are frequently seen in those with membranous nephropathy. Although patients who have documented thromboembolic episodes should be anticoagulated with warfarin until remission of nephrotic syndrome, the use of prophylactic anticoagulation is controversial. A decision analysis study suggested that prophylactic anticoagulation is beneficial for patients with membranous nephropathy.21 Prophylactic anticoagulation is not recommended for all patients, rather a “selective” approach or individualized assessment should be conducted to identify those at high risk [i.e., those with severe nephrotic syndrome and a serum albumin concentration <2.0 to 2.5 g/dL (<20 to 25 g/L)].11 Also at risk are those who require prolonged bedrest, those receiving high-dose intravenous steroid therapy, and individuals who are dehydrated as well as post surgical patients.11
DISEASE PROGRESSION AND TREATMENT CONSIDERATIONS

The course and prognosis of the different glomerular diseases are extremely variable and depend on the underlying etiology. In glomerular diseases with a secondary cause, such as poststreptococcal glomerulonephritis, after the initiating factor is removed, the prognosis of the renal disease is often good. In contrast, the rates of renal function deterioration among the primary glomerulonephritides vary according to the form of glomerulonephritis. The majority of patients with minimal-change disease, IgA nephropathy, and membranous nephropathy have a fairly good prognosis. However, those with focal segmental glomerulosclerosis who are resistant to therapy, as well as those with rapidly progressive glomerulonephritis who are untreated, are likely to experience rapid loss of renal function. In some instances, half of the renal function may be lost within a 3-month period. Certain glomerulonephritides, such as minimal-change nephropathy, are very responsive to treatment. In contrast, for some other types of glomerulonephritides, such as membranous proliferative glomerulonephritis, consistently effective therapy has yet to be found.

Because of the variable courses exhibited by the different glomerulonephritides, specific treatment approaches have been developed for each disease. The natural history of the glomerulonephritis has to be well delineated before a promising regimen can be evaluated, from both therapeutic and economic perspectives. Otherwise, patients will be exposed to unnecessary treatment-related toxicities if they have a type of glomerulonephritis that is likely to undergo spontaneous remission. The potential therapeutic benefits of treatment regimens should always be weighed against the risks to which the patients are being exposed. It is therefore imperative to identify patients who are most likely to benefit from treatment, especially those who have other risk factors that may contribute to the deterioration of their renal function. In those instances in which satisfactory regimens are not available to treat the primary disease, appropriate supportive measures should be employed. Optimization of systemic and glomerular pressure, reducing proteinuria, and possibly controlling hyperlipidemia may all improve the long-term outcome as well as the quality of life of these patients.

Evaluation of Therapeutic Outcomes

Patients should be monitored closely for therapeutic response as well as the development of treatment-related toxicities. Although the rate of renal function deterioration is an important indicator of the long-term success of treatment, resolution of nephrotic and nephritic signs and symptoms associated with the glomerulopathies is an important short-term therapeutic target.

Serum creatinine concentration as well as creatinine clearance should be evaluated prior to and during treatment; 24-hour urine outflow should be collected to determine the extent of proteinuria. Alternatively, the daily urine protein excretion may be estimated from the urinary total protein-to-creatinine concentration ratio. After establishing the correlation between the 24-hour urinary protein excretion and the protein-to-creatinine ratio, single, random urine specimens may be used in place of a 24-hour urine collection. Blood pressure should be monitored periodically to assess the need for and the adequacy of antihypertensive therapy. The pressures should also be evaluated in conjunction with clinical signs and symptoms of edema and fluid overload to gauge the need for volume control as well as diuretic use. For patients with nephrotic syndrome, serum lipid concentrations should be monitored. If the patient has hematuria, urinalysis and a complete blood count should be obtained. The clinician should also be aware of the patient’s appetite and energy level, because these are indicators of the patient’s overall state of well-being. At times, renal biopsy is needed to assess response to treatment and disease progression, to determine future treatment strategy, and to confirm the initial diagnosis.

Patients receiving cytotoxic drug treatment should be evaluated for drug-related toxicities every week during the initial treatment period. After 1 month of treatment, the frequency of monitoring may be reduced. When the patient is on long-term steroid treatment, monthly visits are often required for assessment of both efficacy and toxicities. If a favorable response is obtained after a course of treatment, the patient may be evaluated every 3 to 4 months. The patient’s renal function, proteinuria, urinalysis, blood pressure, lipid profile, and the overall state of health should be assessed during these regular follow-up visits.

INDIVIDUAL GLOMERULOPATHIES

MINIMAL-CHANGE NEPHROPATHY

Epidemiology and Etiology

Minimal-change nephropathy (also termed nil disease or minimal-change disease) is commonly found in children, accounting for about 85% to 90% of all cases of nephrotic syndrome in children between 1 and 4 years of age. The percentage drops gradually to less than 50% after age 10 years and accounts for less than 20% of all cases of idiopathic nephrotic syndrome in adults. Secondary causes of minimal-change nephropathy include NSAIDs, lupus, and various T-cell–related disorders, such as Hodgkin disease and leukemias.

Pathophysiology

Minimal-change disease is characterized by the absence of definitive pathologic changes observed under light and immunofluorescence microscopy. The characteristic lesion in patients with minimal-change disease, as visualized under electron microscopy, is the spreading and fusion of the foot processes of epithelial cells over an unchanged GBM. Lipoid nephrosis is another term that has been used to describe this type of glomerular disease because lipids, as well as renal tubular cells, are found in the urine. The pathogenesis of minimal-change disease is unknown. Altered cell-mediated immunologic response, specifically T-cell dysfunction or changes in the T-cell subpopulations, may be responsible. The activated lymphocytes are thought to secrete lymphokines that reduce the production of anions in the GBM. The permeability of the GBM to plasma albumin is increased through a reduction of electrostatic repulsion. The loss of anionic charges also results in fusion of the epithelial cell foot processes. Other vascular permeability factors, such as hemopexin, IL-4, and vascular endothelial growth factor, also have been suggested to be responsible.

Clinical Presentation

Most patients present initially with edema, frequently acute in onset, following a nonspecific upper respiratory tract infection, allergic reaction, or vaccinations, which might have activated the T lymphocytes. Nephrotic syndrome with massive proteinuria (substantially more than 40 mg/m² per hour for children and greater than 3-3.5 g/day for adults), edema, hypoaalbuminemia, and hyperlipidemia is common. The patient’s weight may increase dramatically because of sodium and fluid retention. Nephritic features, such as gross hematuria, are uncommon. Hypertension and decreased renal function are uncommon in children but are more common in older adults. For some patients, volume depletion may result in mild to moderate azotemia.
Minimal-Change Nephropathy

PHARMACOLOGIC THERAPY

Steroids

**Initial Therapy** Minimal-change disease is most responsive to initial treatment with corticosteroids. In children, steroid therapy is expected to reduce proteinuria in approximately 90% of the patients, with >95% 10-year renal survival. Because of the excellent response to initial therapy with steroids and the prevalence of this glomerular disease in children, reduction of proteinuria secondary to steroid treatment is considered diagnostic for minimal-change disease without the need for biopsy. Prednisone is commonly administered at 60 mg/m² per day initially for 4 to 6 weeks. The dose is then reduced to 40 mg/m² per day every other day for another 4 to 6 weeks, with or without tapering afterward (Fig. 56-3). Proteinuria will disappear in 50% of patients after 1 week and in 90% of patients after 4 weeks of treatment. Different versions of the steroid regimen are available as there is no consensus on the optimal dose and duration. Studies are being conducted to identify the best strategy to induce remission, reduce disease recurrence, and minimize adverse effects of the therapy. Commonly, the initial episode is treated with an extended course (months) of therapy, followed by shorter treatment (weeks) for relapses.

For adults, prednisone 1 mg/kg per day is given initially for 4 weeks with a reduction to 0.75 mg/kg every other day for the next 4 weeks. Proteinuria will disappear in 50% to 60% of patients after 8 weeks of treatment, and complete remission will be attained in 80% of patients after 28 weeks of therapy.

**Relapse** As many as 85% of the patients who respond to initial steroid therapy (steroid sensitive) will experience a relapse of proteinuria, mostly within 6 to 12 months after disease onset. The risk of relapse is affected by the duration of initial steroid therapy. Children who were asymptomatic with proteinuria diagnosed during routine urine screening tend to have less-frequent relapses and a more favorable clinical course. In those who relapse, 50% to 65% may have steroid-responsive relapse episodes over the subsequent 3- to 5-year period. The dose and duration of steroid treatment for the relapse do not influence the subsequent rate of relapse. Commonly, 60 mg/m² per day of prednisone is given until the urine is free of protein for 3 days, to be followed by 4 weeks of alternate-day prednisone at 40 mg/m² per dose.

**Frequent Relapse** Approximately 10% to 20% of children will experience three or four relapses that are responsive to steroid. Half of them will then relapse frequently and become steroid dependent, requiring continuous low-dose alternate-day prednisone to maintain an extended relapse-free period. A small number of patients eventually develop resistance to steroids, and a biopsy done at that time often reveals another pathology such as focal segmental glomerulosclerosis. It is controversial whether minimal-change disease progresses into focal segmental glomerulosclerosis or whether the glomerulosclerosis that was present at the time of initial diagnosis was inadvertently diagnosed as minimal-change nephropathy because of tissue-sampling error during the renal biopsy.

**Cytotoxic Agents**

Cytotoxic agents are often considered for patients who are steroid resistant, as well as for those who require large doses of steroids to sustain remission (steroid dependent). These agents are also beneficial for pediatric patients who experience growth inhibition secondary to chronic use of steroid. Cytotoxic agents are effective in inducing remission and the duration of remission tends to be longer than that induced by steroid. In those patients who relapse after cytotoxic therapy, they may respond to steroid better than before.

Cyclophosphamide at 2 mg/kg per day for 10 to 12 weeks given alone or with prednisone (50 to 75 mg/m²) is very effective in inducing remission and restoring steroid responsiveness for patients who
were previously steroid dependent and then became steroid resistant. Alternatively, chlorambucil at 0.1 to 0.2 mg/kg per day may be used. This agent, however, is associated with more adverse effects than cyclophosphamide. Azathioprine has also been used; however, treatment for 6 to 12 months is often needed before any favorable response is apparent.

The immunosuppressive effect of cytotoxic agents, with or without the concurrent use of steroids, can result in serious infections, which are the primary cause of death for patients with minimal-change nephropathy. Other toxicities associated with cyclophosphamide include gonadal fibrosis, which results in sterility, hemorrhagic cystitis, alopecia, and a potential to develop malignancy in those on long-term treatment.

Cyclosporine

Cyclosporine decreases lymphokine production by activated T lymphocytes and thereby reduces proteinuria by reversing the lymphokine-induced alterations in the anionic charge and permeability of the GBM to albumin. For patients with steroid-sensitive or steroid-dependent disease, cyclosporine induces remission in 80% to 85% of patients. However, the disease-free period is not often sustained, and relapse, which is usually not as responsive to cyclosporine treatment, may occur as soon as the drug is tapered or discontinued. The steroid-sparing effect of cyclosporine is also useful for steroid-dependent patients, especially those who have experienced significant adverse effects.

The usual starting dose of cyclosporine for remission induction is 5 mg/kg per day for adults and 100 to 150 mg/m² per day for children. Similar dosages are used to maintain remission long term. The optimal cyclosporine blood concentrations, as well as the need to monitor them, are controversial. No correlation has been found between the severity of the cyclosporine-induced tubulointerstitial lesions and the mean dose or trough drug concentration. However, monitoring of the area under the serum concentration–time curve has been suggested and target exposures have been proposed. Testing the in vitro sensitivity of peripheral blood lymphocytes to cyclosporine in the presence of a T-cell mitogen may offer a novel method to predict response and individualize therapy.

Adverse events such as rise in serum creatinine, hypertrichosis, and gingival hyperplasia are quite common. Long-term therapy may result in persistent hypertension and progressive renal failure. Cyclosporine should not therefore be given for more than 4 months in the absence of any beneficial effect. Consequently, it is indicated for patients (1) who relapse frequently or are steroid dependent, after failing to respond to a course of cyclophosphamide; (2) for whom cyclophosphamide is contraindicated or when gonadal toxicity is a concern; (3) who are steroid dependent when a “steroid holiday” is needed for catch-up growth and puberty; or (4) who have steroid-resistant disease.

Levamisole

Levamisole, an immunostimulant, can promote the maturation of young T cells and restore the function of T cells and phagocytes when the immune system is depressed. It may also inhibit the production of an immunosuppressive lymphokine. Levamisole was found to have a steroid-sparing effect and was capable of maintaining remission in children who had frequent relapse steroid-dependent nephrotic syndrome. In addition, it is as effective as cyclophosphamide in reducing relapse rate and steroid dosages. The most serious adverse effect of levamisole is neutropenia, which is generally reversible. At present the drug is no longer available in the United States; however, it is still used elsewhere in the world for select steroid-dependent patients.

Mycophenolate Mofetil

Mycophenolate mofetil is an immunosuppressant that can suppress T- and B-cell lymphocyte proliferation, B-lymphocyte antibody production, and expression of adhesion molecules. It is reported to have steroid-sparing effects and to be useful in steroid-dependent patients, as well as in those who fail cytotoxic therapy.

Therapeutic Outcomes

The long-term prognosis of most patients with minimal-change disease is good. The majority of pediatric patients will not experience any relapse of the disease 10 years after the initial onset, and most will be free of the proteinuria after puberty. In adults, an 85% to 90% survival rate is seen 10 years after disease onset. Although this condition may spontaneously remit in up to 70% of untreated adults, life-threatening complications may be associated with untreated nephrotic syndrome. Significant deterioration in renal function is uncommon in both adult and pediatric patients and is observed only in those who are steroid resistant or steroid dependent. Because of the overall favorable outcome of the disease and the relatively uncommon progression into chronic renal failure, aggressive use of cytotoxic agents is not indicated even for most patients with frequent relapses. Toxicities associated with aggressive therapy do not justify the need to induce remission in those patients who fail to respond to steroids and the nonaggressive use of cytotoxic agents. Symptomatic therapy with diuretics to control edema, in conjunction with a low-salt diet and albumin infusion as needed for acute development of anasarca, is often a more rewarding therapeutic approach. NSAIDs and ACEIs may also be used to reduce the proteinuria.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Etiology and Epidemiology

Focal segmental glomerulosclerosis (FSGS) is a clinicopathologic condition that can be idiopathic (primary) or secondary to a variety of causes. FSGS accounts for less than 15% of the cases of idiopathic nephrotic syndrome in children and approximately 15% to 20% in adults; however, it may account for 36% to 80% of the cases in African Americans. The incidence of FSGS has been rapidly increasing, so that it now is the most common glomerular disease that ultimately leads to ESRD. Conditions such as sickle cell disease, cyanotic congenital heart disease, and morbid obesity can induce hemodynamic stress on an initially normal nephron population and result in FSGS. Severe glomerular injury can also be seen in patients with nephropathy associated with heroin abuse, human immunodeficiency virus (HIV) infection, and genetic mutations involving the podocin and WT1 genes. A recent case series identified the association of FSGS and proteinuria in bodybuilders after long-term anabolic steroid abuse. The primary and secondary sclerotic lesions may be morphologically similar, but they represent diseases with different courses and responses to therapy.

Pathophysiology

Sclerotic lesions are characteristically found in some of the glomeruli (focal) and usually involve only a portion of the glomeruli (segmental). Similar to minimal-change disease, fusion of foot processes is commonly seen in those glomeruli that are not sclerotic. It is thought that both minimal-change disease and FSGS share similar pathogenetic mechanisms, with FSGS resulting in severe injury to the glomerular epithelial cells. During the early stage of FSGS, only a small number of glomeruli may have the segmental sclerotic lesion, and the disease may be confined to the
juxtamedullary region. If an inadequate number of glomeruli are sampled during renal biopsy, the diagnosis of FSGS may be missed, or the patient may be thought to have minimal-change disease. Resistance to steroid therapy may thus be one of the first clues that the patient, indeed, has FSGS rather than minimal-change disease. Alternatively, a patient may have the steroid-sensitive minimal-change disease initially, which subsequently progresses to steroid-resistant FSGS.

**Clinical Presentation**

Almost all the patients present with proteinuria, and many of them have all the features of nephrotic syndrome. The proteinuria is nonselective, containing albumin and other higher-molecular-weight proteins, and is usually less severe when compared to patients who have minimal-change disease. Hypertension, microscopic hematuria, and renal dysfunction may be seen in up to half of the patients. Reduced renal function becomes more prevalent as the disease progresses.

The presenting clinical features in nephrotic adults with minimal-change nephropathy can be indistinguishable from that of FSGS, and renal biopsy is therefore critical in the diagnosis of adults with nephrotic syndrome. African Americans have a fourfold higher risk of developing FSGS than white or Asian patients. They tend to develop the disease earlier and present with nephrotic range proteinuria more often. They are less responsive to steroids and are more likely to experience a rapid decline in renal function, resulting in ESRD.

**TREATMENT**

**Focal Segmental Glomerulosclerosis**

**PHARMACOLOGIC THERAPY**

**Steroids**

The treatment of FSGS is controversial because of the lack of data from randomized, prospective, controlled trials. A course of prednisone (1 to 2 mg/kg per day) with tapering after 3 to 4 months of treatment is first used for nephrotic patients. Urinary protein excretion and serum albumin concentration should be monitored to assess efficacy. The median time to induce complete remission is 3 to 4 months, although 5 to 9 months may be needed in some patients. In general, 30% to 40% of all patients can be expected to attain complete remission; for those who are not responding, treatment should be continued for 6 months before they are considered steroid resistant.

If the patient develops a relapse after an adequate response to the initial treatment, a second course of steroids is usually sufficient. However, if relapse occurs frequently, cytotoxic agents or cyclosporine would be indicated.

For patients who are not nephrotic, their relatively favorable prognosis does not support using steroids or other immunosuppressive agents. However, close follow-up and good blood pressure control with ACEIs are necessary to minimize disease progression.

Most of the studies conducted thus far include mostly white patients. In a recent retrospective review of 72 patients that included 65 African-American patients, steroid use was not associated with renal survival or the induction of proteinuria remission. The initial creatinine level, blood pressure, and severity of renal lesion are significant factors for renal survival. About one third of the patients who received steroids developed complications such as diabetes and significant weight gain.

**Cytotoxic Agents**

When used with steroids during initial therapy, cytotoxic agents were not found to offer any additional beneficial effect. For those patients who are not responding to steroids during initial therapy, cytotoxic agents such as cyclophosphamide (2 mg/kg/day) and chlorambucil (0.1 to 0.2 mg/kg/day) have been used with pulse methylprednisolone to induce remission. Response rates as high as 66% have been reported in uncontrolled trials, although such favorable responses have not been universally observed.

**Calcineurin and Rapamycin Inhibitors**

In steroid-resistant patients, cyclosporine therapy has produced a complete or partial remission in 70% of patients, with a relapse rate of 47%. Encouraging results have also been reported with the concurrent use of cyclosporine and steroid. Adverse effects of cyclosporine commonly include gingival hyperplasia, hypertrichosis, hypertension, and renal insufficiency. In an attempt to minimize the long-term side effects, a regimen that included periodic cyclosporine dose reduction when given with steroid, cyclophosphamide, and mycophenolate mofetil was developed, and favorable effects were observed. Tacrolimus has also been used to induce remission and reduce proteinuria for patients with refractory disease. The effect of sirolimus on proteinuria has been found to be conflicting, however, it may cause a rapid decline in GFR, and hence, its use for FSGS is not recommended.

**Mycophenolate Mofetil**

Mycophenolate mofetil has been reported to have favorable effects for patients who were steroid resistant, many of whom had failed to respond to other cytotoxic agents and cyclosporine. Forty-four percent of the patients had reduced proteinuria and the improvement was sustained in 50% for up to 1 year. Deterioration of renal function was not observed. Other investigators have reported similar experiences. Further studies are needed to define the role of this agent among the various treatment options.

**Symptomatic Therapy**

Because of the lack of a consistently effective regimen for primary FSGS, many patients with mild disease are treated conservatively. ACEIs and ARBs are effective in reducing proteinuria and in stabilizing renal function in many patients with primary or secondary FSGS. For patients who have nephrotic range proteinuria, an elevated serum creatinine concentration and interstitial scarring on biopsy, corticosteroids with or without immunosuppressive agents are often used.

**THERAPEUTIC OUTCOMES**

ESRD develops within 10 years in 10% or less of the 30% to 50% of adults and children who had attained complete remission. For those patients who are resistant to therapy, the rate of renal function deterioration to ESRD may be rapid, within 1 year, or slow, over as long as 10 to 20 years; approximately 50% develop ESRD within 10 years. Those patients with severe proteinuria (>10 to 15 g/day), high serum creatinine concentration at diagnosis, initial steroid resistance, or interstitial fibrosis on renal biopsy are likely to have a more rapid decline in renal function. African-American patients may also have a higher risk. Kidney transplantation is often indicated for those patients who develop ESRD; however, FSGS has recurred in 20% to 50% of the renal
allografts soon after transplantation. Children and those with severe disease or rapid progression to ESRD prior to transplantation are more likely to experience a recurrence. The proteinuria may reappear within hours after transplantation, and graft failure may occur in one third to one half of the patients. The median time to recurrence was reported to be 14 days in one study. Although cyclosporine is ineffective in preventing the recurrence of nephrotic syndrome after transplantation, a high dose of the agent (up to 35 mg/kg per day) induces a remission of the recurrent disease. ACEIs and plasmapheresis are also used to prolong graft survival. The effectiveness of these therapies and the rapid recurrence of the disease in the transplanted kidney substantiate the possibility that a circulating humoral mediator is responsible for the nephropathy.

MEMBRANOUS NEPHROPATHY

Etiology and Epidemiology
Membranous nephropathy is the most common disorder responsible for idiopathic nephrotic syndrome in adults, accounting for about 20% to 25% of cases. It is also a frequent cause of renal failure secondary to glomerulonephritis. The hallmark histologic features of membranous nephropathy are glomerular capillary wall thickening with subepithelial deposits under light and electron microscopy. Most cases are idiopathic, but approximately 25% of adults and 80% of children have secondary causes. In the United States, the most common etiologies are autoimmune diseases (e.g., lupus), infection (e.g., hepatitis B and C), syphilis, neoplasm (e.g., carcinoma of the lung, breast, gastrointestinal tract, or kidney), and medications (e.g., gold, penicillamine, or captopril). Malaria and schistosomiasis are common causes in other parts of the world. De novo membranous nephropathy can also occur in the allografts of renal transplant patients. Because the responses to therapy as well as the prognosis for idiopathic and secondary membranous nephropathy are different, it is important to identify any potential underlying causes for the nephropathy prior to treatment. Although this glomerular disease can occur at any age, the peak incidence is between ages 30 and 50 years and is especially likely in patients older than age 50 years who present with nephrotic syndrome.

Pathophysiology
Examination of kidney tissue under light microscopy reveals normal mesangium and normocellularity. The glomerular capillary wall may be thickened in well-developed lesions. In the advanced stage, the capillary wall is markedly thickened, and intramembranous deposits are found. Progressive changes in capillary lumen patency parallel those in the GBM, resulting in glomerulosclerosis with capillary collapse and tubular atrophy in end-stage membranous nephropathy. Immunofluorescence microscopy shows strong capillary wall staining of IgG and C3 on the epithelial side of the basement membrane. Antibody-mediated immune injury appears to be the main pathogenetic mechanism. The immune complex can be formed in situ or deposited from circulating immune complexes.

Clinical Presentation
Most patients with membranous nephropathy present with heavy proteinuria (exceeding 3.5 g/day). Those patients excreting large amounts of IgG and α-2-microglobulin, indicating more significant tubulointerstitial damage, have a lower remission rate and are more likely to progress toward renal failure.

The signs and symptoms are usually insidious in onset and may consist of anorexia, malaise, edema, anasarca, or ascites, and pericardial and pleural effusions may also be present. As a result of a hypercoagulable state, pulmonary embolism may develop but rarely results in death. The incidence of renal vein thrombosis varies from 5% to 62%, and membranous nephropathy should be suspected when there is a sudden onset of hematuria, loin pain, pulmonary embolus, fluctuating or worsening proteinuria or GFR, renal tubular acidosis, or an increase in leg edema. Hypertension is found in approximately 30% of patients and is more common with renal insufficiency or in advanced disease.

In addition to heavy proteinuria, urinalysis often reveals lipiduria and oval fat bodies. Microhematuria is seen in fewer than 25% of patients, and gross hematuria and red cell casts are rare. In idiopathic membranous nephropathy, the serum complement concentrations are normal. Low levels of complement should alert one to search for secondary causes, such as lupus, hepatitis B infection, or an alternative diagnosis. Similarly, antinuclear antibodies, anti-DNA antibodies, rheumatoid factor, hepatitis B serologies, and serum cryoglobulins are generally negative in idiopathic membranous nephropathy. Occult malignancy has been found in as many as 10% of elderly patients with membranous nephropathy.

The natural course of idiopathic membranous nephropathy is variable. Up to 30% of the patients experience spontaneous remission, commonly within 2 years of disease onset. Half of the remaining patients have persistent proteinuria with long-term preservation of renal function, while the other half has gradual loss of renal function. Heavy proteinuria (>10 g/day), male gender, elevated serum creatinine concentration at the time of presentation; poorly controlled hypertension, advanced age at onset of disease, non-Asian race, certain human leukocyte antigen phenotypes, and tubulointerstitial fibrosis on initial renal biopsy are associated with progressive renal disease. A predictive algorithm, incorporating the level of proteinuria, initial creatinine clearance, as well as the slope of renal function decline over 6 months, has been developed to determine the risk for disease progression.

In general, patients with idiopathic membranous nephropathy have a relatively benign course with mean 10-year survival of approximately 70%. Those who present with persistent nonnephrotic proteinuria seldom develop renal insufficiency and have a normal life expectancy. Fewer than 10% of patients develop a remitting and relapsing course. The prognosis for secondary membranous nephropathy depends on the underlying cause. Remission occurs when the infection resolves or when the causative medication is withdrawn.

TREATMENT

Membranous Nephropathy

The treatment of idiopathic membranous nephropathy is controversial and ranges from supportive therapy to immunosuppression. Conservative management of patients with mild disease includes edema control with salt restriction and diuretics and reduction of proteinuria with protein restriction and ACEIs (Fig. 56-4). Management of hypertension and hyperlipidemia is required for most patients, whereas prophylactic anticoagulation, despite having benefits shown to outweigh the risks, is usually given only for patients with renal vein thrombosis or documented pulmonary embolus.

PHARMACOLOGIC THERAPY

Steroids
Remission of proteinuria, whether spontaneously or treatment related, may confer a good prognosis. Corticosteroids alone were
ineffective in improving proteinuria remission rate in all controlled trials and in preventing progression in all but one study. The result of a metaanalysis also confirmed the lack of efficacy of steroids when used alone.

### Cytotoxic Agents

Cytotoxic agents, when used in conjunction with corticosteroids, are effective in increasing the remission rate of proteinuria and preserving renal function. Ponticelli and colleagues devised such a regimen by combining intravenous methylprednisolone (1 g) for 3 days followed by oral methylprednisolone (0.4 mg/kg) for the subsequent 27 days of months 1, 3, and 5. Oral chlorambucil (0.2 mg/kg) is to be given daily in months 2, 4, and 6. The 10-year renal survival was increased to 92% when compared with 60% in the control group. They later substituted cyclophosphamide (2.5 mg/kg per day) for chlorambucil, which resulted in similar rates of proteinuria remission and relapse, but with fewer serious side effects in those who received cyclophosphamide.

Results from a recent metaanalysis of randomized, controlled trials affirmed that cytotoxic agents, but not steroids, are effective in reducing nephrotic-range proteinuria, with cyclophosphamide having fewer adverse effects than chlorambucil.

### Cyclosporine

A controlled trial found that cyclosporine, given at a dose of 3 to 4 mg/kg/day for 6 months, was effective for patients with medium risk for disease progression. For patients with severe nephrotic syndrome and deteriorating renal function who do not respond to cytotoxic therapy, cyclosporine may offer some benefits; however, the risk for cyclosporine nephrotoxicity is of concern, especially during long-term therapy. A 12-month course of cyclosporine (mean dose: 3.8 mg/kg/day) was found to reduce proteinuria as well as the rate of renal deterioration. In a recent study of 41 patients who received cyclosporine, many with concurrent steroid and ACEI therapy, the median treatment time to complete remission was 225 days among the 34% of patients who attained complete remission. During such long-term treatment, hypertension may be exacerbated and the serum creatinine concentration may be increased because of nephrotoxicity. When the renal function declines, the dose of cyclosporine should be reduced.

### Alternative Therapeutic Options

Because spontaneous remission is common and only approximately 25% of patients with new-onset idiopathic membranous nephropathy ultimately develop ESRD in 20 to 30 years, it is prudent not to aggressively treat all patients at the onset of the disease. Patients who have a low risk for renal disease progression can be managed with observation and symptomatic therapy. Normalizing the blood pressure and reducing proteinuria with ACEIs and/or ARBs are important as both hypertension and proteinuria are independent risk factors for the progression of renal failure. Patients with low risk for renal disease progression include children 2 to 16 years of age, adult males with proteinuria less than 2 g/day, or adult females with proteinuria less than 5 g/day and normal renal function. In contrast, patients who have a high risk of developing renal failure, including those with proteinuria greater than 10 g/day with or without impaired renal function, and patients with symptomatic nephrotic syndrome with a plasma albumin of less than 2 g/dL (20 g/L) should be aggressively treated to induce remission. An alkylating agent such as cyclophosphamide or chlorambucil, combined with steroids, should be given to induce remission. Recently, rituximab was shown to be effective in treating small number of patients, while eculizumab was not effective. Mycophenolate mofetil was not more effective or better tolerated than cyclophosphamide. Tetracosactide, a synthetic analog of adrenocorticotropic hormone, has also been shown in small studies to offer results superior to the cytotoxic–steroid combination regimen.

The cytotoxic–steroid combination regimen may be effective in inducing remission in the 30% to 40% of the medium-risk patients who relapse within 2 years after treatment discontinuation. Alternately, cyclosporine may be used with similar effectiveness. The cyclophosphamide–steroid combination should also be used for relapse in high-risk patients.

For patients with a transplanted kidney, both de novo and recurrent membranous nephropathy may occur. Patients with primary membranous nephropathy are more at risk. Recurrence is typically associated with nephrotic syndrome and a high risk of allograft failure from disease and/or rejection.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Etiology, Epidemiology, and Pathophysiology

Membranoproliferative glomerulonephritis (MPGN) is one of the least-common renal morphologic entities that occur in older children and adults. For some unclear reason, the incidence of MPGN has been decreasing over the past few decades in the United States and Europe. However, in Africa and Asia, idiopathic MPGN is still common, perhaps secondary to exposure to unrecognized infectious and parasitic agents.

The several types of MPGN are classified according to the pathologic features. Type I MPGN, also known as mesangiocapillary glomerulonephritis, is characterized by diffuse thickening of glomerular capillary walls and mesangial hypercellularity. Immune complexes are presumed to have a major role in the pathogenesis of type I MPGN, which is the most common type of primary, idiopathic MPGN.

Type II MPGN is also known as dense-deposit disease (DDD) because of the presence of dense deposits of C3 within the GBM, which gives rise to a ribbon-like appearance. Other variants of the disease include type III MPGN, which is seen rarely and consists of subendothelial and subepithelial deposits with lamination and disruption of the lamina densa of the GBM.

Type I MPGN is a slowly progressive disease that accounts for 80% of all MPGN, but only 5% to 15% of all cases of nephrotic syndrome seen in pediatric and adult patients. It occurs most frequently for patients between 5 and 30 years of age, and because remissions are rare, many patients eventually develop ESRD. The renal survival is 60% to 65% at 10 years, and the presence of nephrotic syndrome, interstitial disease, and hypertension are poor prognostic indicators. Type II MPGN is a more aggressive disease that constitutes approximately 15% of all patients with MPGN. Only 20% of patients remain stable for more than a few years, and the median time before the development of ESRD is 7 years.

Clinical Presentation

Nephrotic syndrome is the most common presenting condition although some patients may also have a nephritic component (hematuria), hypertension, and renal insufficiency. Hypocomplementemia is commonly seen.

TREATMENT

Membranoproliferative Glomerulonephritis

■ STEROIDS

The efficacy of corticosteroids, cyclophosphamide, antiplatelet drugs, and anticoagulants has been evaluated for the treatment of MPGN. In children, prednisone 40 mg/m² given on alternate days is effective, when compared with placebo, in reducing the decline in GFR. This observation was confirmed by other uncontrolled studies. Consequently, prednisone should be given for 6 to 12 months to children with MPGN, proteinuria (more than 3 g/day), and/or impaired renal function. Other studies suggest that this regimen may also be beneficial in children with mild proteinuria.

Although the effect of steroids has not been proven in adults, antiplatelet drugs, such as dipyridamole and aspirin, as well as warfarin, were found in randomized controlled trials to reduce proteinuria but had no effect on GFR. Subcutaneous heparin has also been used in a small number of patients with favorable results. Adult patients with idiopathic MPGN, heavy proteinuria, and/or impaired renal function should be given dipyridamole or aspirin. Unfortunately, no controlled study comparing the effect of steroids with antiplatelet agents is yet available.

■ CYTOTOXIC AGENTS

Cyclophosphamide and azathioprine were found to have no beneficial effect. Cyclosporine was evaluated in a limited number of patients with MPGN with some beneficial effect; however, the trials were not controlled or randomized. In addition, the risks for developing adverse effects were high. Figure 56–5 presents an algorithm for treatment and follow-up of MPGN.

■ ANTIPLATELET AGENTS

Although several studies have shown dipyridamole and aspirin to reduce proteinuria, reduction of GFR decline was not generally observed. Consequently, antiplatelet therapy should be considered.

as a viable option only for those patients with significant proteinuria. There should be periodic follow up of patients to assess proteinuria and renal function.

Since steroids are not known to be effective for type II disease other yet-to-be-proven strategies such as rituximab, eculizumab, sulodexide, and plasma infusion or exchange may be considered. It is difficult to conduct large-scale controlled trials for MPGN because of the low incidence of the disease. Based on the available studies, many of the drugs evaluated do not have any consistent, beneficial effect on renal function and proteinuria. Renal transplantation is an alternative; however, the recurrence rate is close to 100% for type II MPGN and is approximately 20% to 30% for type I MPGN. Half of the allografts ultimately fail.

**IMMUNOGLOBULIN A NEPHROPATHY**

**Etiology and Epidemiology**

IgA nephropathy, also known as Berger disease, was first described in France in 1968. It now is the most common primary glomerulonephritis in the world and accounts for 10% of patients with ESRD in many countries. The prevalence among patients with glomerulonephritis or patients who had kidney biopsy varies from as high as 50% in Japan and East Asia to 10% to 30% in Europe. In the United States, the overall prevalence is approximately 10% to 15% but is as high as 35% among Native Americans living in New Mexico. These differences in prevalence may reflect variations in genetic predisposition, as well as the criteria used for urinary screening and kidney biopsy.

IgA nephropathy is more frequently seen in younger adults and is two to six times more common in males than in females. It is uncommon in blacks, both in the United States and in Africa. IgA nephropathy was once thought to be a benign disease presenting with asymptomatic hematuria; however, its ability to present with any clinical syndrome associated with glomerular disease is now recognized. Some patients will develop ESRD over variable periods of time.

**Pathophysiology**

Primary IgA nephropathy is an immune-complex–mediated disease in which IgA deposits and other pathologic lesions are found in kidney tissues. In contrast, Henoch-Schönlein purpura, a systemic disease that is believed to be closely linked to IgA nephropathy, shares similar immunohistologic findings in the kidneys. Both typically have vasculitis affecting the joints, skin, and gastrointestinal tract, which may result from the same pathologic process of IgA nephropathy. The diagnosis of IgA nephropathy is established by the presence of mesangial IgA deposits upon immunofluorescence examination of the kidney biopsy. The IgA immune complex, composed of IgA antibody bound with an environmental antigen, such as a virus, bacteria, or food substances, is presumed deposited from the systemic circulation. Alternately, the complex may be formed in situ, with the IgA antibody bound with an endogenous antigen in the mesangium. In the mesangium, IgA can bind with receptors on the mesangial cells to induce proliferation and cytokine production. In addition, IgA can activate complement through the alternate pathway to induce glomerular damage. The extent of the injury depends on the characteristics of the IgA that favor mesangial deposition, the susceptibility of the mesangium toward deposition, the ability of the patient to mount an inflammatory response to the deposits, and the response of the kidney to the injury in a way that favors progressive renal damage.

**Clinical Presentation**

IgA nephropathy commonly presents in the second and third decades of life, but it can occur at any age. Many patients have microscopic hematuria and proteinuria for years, persistently or intermittently, during the early stages of the disease. About half of the patients present with gross hematuria concurrent with an infection, commonly in the upper respiratory tract. The hematuria may occur 1 to 2 days after the onset of infection symptoms, which is different from the 10- to 14-day delay seen after the pharyngitis in poststreptococcal glomerulonephritis. Proteinuria is common, and nephrotic range often indicates advanced disease. Hypertension and edema are infrequent but are common in poststreptococcal glomerulonephritis.

Renal dysfunction is uncommon at the initial presentation; however, approximately 10% to 20% of the patients develop ESRD within 10 years, and 30% develop it after 20 years. Hypertension, severe proteinuria, renal function impairment, old age, and the severity of histologic lesions are all predictive factors for poor long-term outcome.

**TREATMENT**

**Immunoglobulin A Nephropathy**

Spontaneous remission is seen in only 10% to 25% of children and 5% to 7.5% of adults. Unfortunately, no therapy is known to be consistently effective for the treatment of IgA nephropathy. Because of the slow progression of the disease to ESRD, it is very difficult to conduct trials to evaluate the long-term effectiveness of specific treatments. The lack of understanding of the pathogenetic mechanisms and the unavailability of appropriate animal models severely limit the development of rational treatment regimens.

**NONPHARMACOLOGIC THERAPY: LOW-GLUTEN DIET AND TONSILLECTOMY**

Restriction of dietary gluten is effective for patients with celiac disease but not for patients with no identifiable nongluten antigens. Removal of the tonsils, which produce IgA, may contribute to IgA nephropathy, may reduce proteinuria and hematuria. This is especially helpful for patients who developed recurrent macroscopic hematuria as provoked by bacterial tonsillitis. There are limited studies to show the long-term renoprotective effects of tonsillectomy; however, larger studies with longer follow-up are needed to affirm such beneficial effect.

**PHENYTOIN**

Phenytoin was evaluated because of its ability to reduce the amount of polymeric IgA in the circulation. Although it reduced serum IgA concentrations and frequency of macroscopic hematuria, the glomerular lesions deteriorated in some of the patients and the drug is not generally used nowadays.

**CORTICOSTEROIDS**

Corticosteroids with or without immunosuppressive agents have been used to treat IgA nephropathy for many years. A recent metaanalysis of available trials showed that steroid therapy is associated with reduction in proteinuria, risk for progression to ESRD, as well as the rate of renal function deterioration. Low-dose, short-term (<3 months) steroid therapy is not expected to yield favorable results. In contrast, larger doses of steroids (IV methylprednisolone 1g/day for 3 days at months 1, 3, and 5 and oral prednisone 0.5 mg/kg every other day for 6 months) were able to reduce proteinuria and renal function deterioration. However, the dose of...
the steroids and the risk for toxicity might be considered high by many.76 Patients with nephrotic range proteinuria and impaired renal function are likely candidates for steroid therapy; however, the responses to such treatment are not favorable.

■ CYTOTOXIC AGENTS

Several studies have evaluated the efficacy of azathioprine and cyclophosphamide. In some of the studies, cyclophosphamide was used in conjunction with dipyridamole, heparin and warfarin. It is difficult to assess which of these agents contributed to the limited favorable effects observed. In addition, in many of these studies, blood pressure control and ACE inhibition were not always optimal. At present, there is no clear evidence to support the use of these cytotoxic agents for IgA nephropathy, except perhaps for those patients with advanced rapidly progressive disease.78

![CLINICAL CONTROVERSY Image](CLINICAL CONTROVERSY Image)

Is fish oil effective for IgA nephropathy?

■ FISH OIL

The third approach is to reduce glomerular inflammation and glomerulosclerosis induced by IgA deposits. Antiinflammatory agents, antiplatelet drugs, and anticoagulants have been tried without success to decrease the production or action of mediators responsible for IgA immune-complex–induced glomerular damage.

However, the n-3 fatty acids in fish oil reduce the production or action of prostaglandins and leukotrienes, thus limiting the renal damage caused by inflammation, platelet aggregation, and vasoconstriction.74 In a controlled trial on patients with heavy proteinuria and mildly impaired renal function, daily use of fish oil delayed the progression of renal failure with modest reduction in proteinuria.75 A metaanalysis of five controlled studies indicated that a minor, but not statistically significant, beneficial effect on renal function may be observed.76 Results from several recent studies failed to confirm the beneficial effects reported earlier, and further studies are needed to confirm the role as well as the optimal dose. In many of the studies, 4 to 12 g/day were given for 2 or more years. Some of the fish oil preparations are rich in cholesterol; thus, it is appropriate to monitor the LDL cholesterol levels for patients receiving therapy.

■ ANGIOTENSIN-CONVERTING ENZYME INHIBITION

Because hypertension is a negative prognostic indicator of IgA nephropathy and many of these patients already have left ventricular diastolic dysfunction despite being normotensive, early antihypertensive intervention with ACEIs or ARBs is important.66,80 If a single agent is insufficient to reduce proteinuria and maintain blood pressure at 125/75 mm Hg, combined use of ACEI and ARB should be instituted.81

■ ALTERNATIVE THERAPEUTIC APPROACHES

Patients with IgA nephropathy have abnormal production of IgA and several different immunoglobulins. Immunoglobulins, administered intravenously initially and then intramuscularly, may have beneficial effects through immunomodulation, increased catabolism of autoantibodies, and blockade of receptors.77 The doses in this experimental trial, which has not been independently replicated, were very high: 1 g/kg/day for 2 days IV for the first three months, then 0.35 mL/kg IM every 15 days for the next six months. Plasmapheresis with albumin replacement was performed before the 2- to 12-hour IV infusions to avoid serum sickness. Reduction in proteinuria, hematuria, GFR decline, and histologic activity index were observed for 11 patients with a progressive course of the disease. Renal survival was prolonged for eight of these patients who were followed for 3 to 10 years.78 Larger, randomized, controlled trials are needed before one can recommend this regimen with confidence.

Urokinase, danazol, dapsone, sodium cromoglycate, and plasma exchange have also been evaluated, but none is consistently effective nor shown to affect renal function.7,17 Cyclosporine treatment was found in a limited number of studies to reduce proteinuria; however, renal function decreased during treatment. Consequently, its use is limited by the potential for nephrotoxicity.24,77

The HMG-CoA reductase inhibitor fluvastatin was reported to reduce urinary protein excretion in moderately proteinuric (0.6 to 1.6 g/day) patients who had IgA nephropathy with normal renal function.79 Creatinine clearance remained stable during the 6-month study. Although evaluation for a longer term in a larger patient population is needed to confirm this beneficial effect, statin use is an obvious choice for hyperlipidemic patients with IgA.

Antiplatelet agents are commonly used in Japan and rarely outside of Asia for IgA nephropathy.80 A recent metaanalysis of seven trials (four in Japan and three in Hong Kong) revealed that these agents reduced proteinuria and stabilized renal function.81 Mycophenolate mofetil and several new strategies are being evaluated as experimental treatments for IgA nephropathy on the premise that they may reduce IgA synthesis and mesangial uptake and/or suppress the effects of proinflammatory or profibrogenic mediators.81

Normotensive patients with normal renal function, isolated microhematuria, and proteinuria less than 1 g/day should be observed closely without specific treatment.82 Patients with minimal proteinuria of 0.5 to 1 g/day receive fish oil and an ACEI or ARB (Fig. 56–6) to attain BP of <103/80 mmHg and urinary protein excretion of <500 mg/day.83 Combined ACEI and ARB seems to be more effective than monotherapy. Because corticosteroids reduce proteinuria, a course of alternate-day prednisone (1 mg/kg/day) with subsequent tapering is indicated for patients with proteinuria greater than 3 g/day who have good renal function (>70 mL/min [>1.17 mL/s]).71 A more aggressive IV or oral steroid regimen may be considered, even though its efficacy has not been definitively established. For patients with a slow progressive decline in creatinine clearance [<70 mL/min (<1.17 mL/s)], fish oil should be given. Azathioprine, cyclophosphamide, mycophenolate mofetil, or dipyridamole/warfarin therapy may also be used, although

![FIGURE 56-6 Image](FIGURE 56-6 Image)

Treatment algorithm for biopsy-proven IgA nephropathy. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; GFR, glomerular filtration rate.) (Modified from reference 71.)
the efficacy of these agents has not been firmly established. If the patient experiences rapid GFR decline of more than 2 mL/min (0.033 mL/s) per month, immunoglobulin therapy may be considered despite the fact that only limited data are available. Other therapies that may be considered for these patients include pulse steroids, a cyclophosphamide–steroid combination, mycophenolate mofetil, and plasmapheresis.\textsuperscript{24,69,71,82}

### THERAPEUTIC OUTCOMES

Urinary protein excretion and the mean arterial blood pressure at follow-up correlate well with the progression of disease. The risk of developing ESRD is proportional to the amount of proteinuria, under the influence of ACEI and ARB therapy, after 1 year of follow-up.\textsuperscript{83} For those patients who develop end-stage renal failure, transplantation is appropriate, especially for young adults. Recurrence of IgA mesangial deposits in the renal allograft may occur in up to 50% of patients in 5 years and be universally present at 10 years or more posttransplant, but the recurrence of clinical disease is only approximately 10% to 15%.\textsuperscript{69} There is also no correlation between the aggressiveness of the primary disease and the rate of recurrence.\textsuperscript{83} Use of ACEI may improve graft survival\textsuperscript{46} while immunosuppression with corticosteroids, azathioprine, and/or cyclosporine is not expected to prevent the recurrent nephropathy.

### LUPUS NEPHRITIS

#### Etiology and Epidemiology

Glomerulonephritis is one of the most serious complications of systemic lupus erythematosus (SLE) and accounts for much of the morbidity and mortality of patients afflicted with the disease. SLE predominantly affects young women between 15 and 40 years of age, with an incidence of 1 in 2,000 women in the United States. African Americans are more susceptible; they develop the disease at a younger age, have nephritis earlier in the course, and are more likely to progress to end-stage kidney disease.

The renal manifestations of lupus nephritis are variable and encompass a wide spectrum of histopathologic lesions.\textsuperscript{85} The underlying histopathology is associated with different processes and responses to therapy, which can not be predicted solely based on clinical manifestations. Thus, a renal biopsy is required to assess the severity of the disease and to predict the short-term and long-term outcomes associated with therapy. Drugs, such as hydralazine and procainamide, are known to precipitate a lupus syndrome; however, they are unlikely to cause disease that affects the kidney.

#### Pathophysiology

Immune complex deposits, whether formed in the circulation or in situ, can be found in various regions of the glomerulus, as well as the peritubular interstitium and vasculature outside the glomerulus. Based on light, immunofluorescence, and electron microscopy findings, lupus nephritis can be categorized into six World Health Organization (WHO) classes: I, normal; II, mesangial; III, focal proliferative; IV, diffuse proliferative; V, membranous; and VI, advanced sclerosing.\textsuperscript{86} In an attempt to enhance the predictive values of the histologic findings, semiquantitative assessments of active lesions and sclerotic changes are used to determine activity index and chronicity index, respectively. In 2003, the ISN/RPS (International Society of Nephrology/Renal Pathology Society) classification was developed to reduce interobserver reproducibility and provide a practical and standardized approach to biopsy interpretation so that outcome data can be compared worldwide.\textsuperscript{87}

The hallmark feature in the pathogenesis of SLE is B-cell hyperactivity and the dysregulated production of autoantibodies against multiple antigens in the body, including DNA and various ribonucleoproteins.\textsuperscript{85,88} The size and location of the immune complexes in the glomerulus correlate with the nature and severity of renal injury. Deposition of small numbers of stable immune complexes of intermediate size in the mesangium tends to produce less severe inflammation in the glomerulus. The sequestration of the immune complexes in the mesangium prevents them from activating inflammatory mediators. Hence, the lesion is noninflammatory in nature. In contrast, large numbers of intermediate-sized or large immune complexes result in infiltration of inflammatory cells and release of necrotizing enzymes.

#### Clinical Presentation

Females have a higher risk for developing lupus, especially in the adult years. Nephritis is commonly seen within the first 4 years of diagnosis of SLE but may also be the first manifestation of the disease. The clinical presentation ranges from minimal hematuria and proteinuria to severe, rapidly progressive diffuse glomerulonephritis. Proteinuria is very common, and nephrotic syndrome is seen in most patients with membranous lesions. Microscopic hematuria is almost always present, whereas macroscopic hematuria, which commonly indicates severe renal involvement, is rare. Active urinary sediments (red cell casts, dysmorphic red cells, and hematuria) are suggestive of the diffuse proliferative lesion.\textsuperscript{85} Hypertension is present in 25% to 45% of patients and is associated with a worse prognosis. Recent studies affirm the poor prognosis and higher risk for renal involvement among African-American and Mexican-American patients, compared with white and Puerto Rican–Hispanic patients, due to the greater severity of disease at baseline, presence of certain autoantibodies, and socioeconomic considerations.\textsuperscript{89} Other conditions found to be associated with poor prognosis include elevated serum creatinine concentration, heavy proteinuria, anemia [hematocrit <26% (<0.26)], and disease onset during childhood or in those >60 years of age. Most patients have hypocomplementemia and increased antibody titers for anti-double-stranded DNA, particularly those with focal or diffuse proliferative lesions. Serum creatinine concentration at the time of diagnosis is most predictive of short-term outcome.

#### TREATMENT

**Lupus Nephritis**

The choice of therapy depends on the underlying lesion and the activity, as well as the chronicity indices. Acute life-threatening disease involving multiple organs requires induction treatment that can suppress the disease promptly. In contrast, long-term management of chronic indolent disease requires therapy with more acceptable side-effect profiles. Corticosteroids are the cornerstone of therapy. However, for severe lupus nephritis, primarily the diffuse proliferative type, alkylating agents may be needed to reduce or prevent the progression to ESRD. Newer alternatives with fewer side effects are now available.

Optimal blood pressure control is important. ACE inhibitor or ARB has been shown to reduce proteinuria. Patients with normal renal function and less than 2 g of proteinuria usually do not require therapy, except for the management of extrarenal lupus manifestations. The prognosis of these patients is generally good, and renal biopsy can be delayed. However, close follow-up of renal function and urinalysis is required.
ACUTE INDUCTION TREATMENT

Steroids and Cytotoxic Agents

Patients with more than 2 g of proteinuria, deteriorating renal function, and/or active urinary sediments require a renal biopsy to define the underlying lesion and determine the activity and chronicity of disease. Patients with proliferative lesions, class IV and class III with subendothelial deposits and signs of severe disease activity, should be treated with pulse intravenous methylprednisolone followed by low-dose oral steroids. Cyclophosphamide is used concurrently because it is a powerful B-cell inhibitor and can suppress the resynthesis of autoantibodies to normal levels. Combined use of intravenous cyclophosphamide and methylprednisolone is more effective than either agent alone in inducing remission. Cyclophosphamide is given orally in some of the regimens. Azathioprine has also been used in conjunction with cyclophosphamide. The risk for adverse events, such as infection, gonadal damage, amenorrhea, and cervical dysplasia, and malignancy is increased with the cytotoxic regimens. Studies show that cyclophosphamide toxicities may be related to the cumulative doses rather than the route of administration. Because oral doses of cyclophosphamide tend to accrue easily, it is prudent to use it only for those who are high risk and had failed other therapies.

Mycophenolate Mofetil

CLINICAL CONTROVERSY

Should mycophenolate mofetil be used in place of cyclophosphamide for lupus nephritis?

Several trials have found that mycophenolate mofetil with concurrent steroid therapy is an effective agent for induction therapy. It was as effective as cyclophosphamide in inducing remission but with fewer side effects. A recent meta-analysis of the literature corroborates to the fact that it is an excellent agent for the induction of remission and that continued use may reduce risk for death or development of ESRD. However, many of these trials were conducted in Asia, and the results may not be reproducible in American patients. Two recent trials that included African Americans, who are known to have a poorer prognosis, also show that mycophenolate mofetil was more efficacious than intravenous cyclophosphamide and resulted in fewer adverse effects. Based on these data, mycophenolate mofetil seems to be a viable alternative to intravenous cyclophosphamide, especially for patients with mild to moderate focal or diffuse lupus nephritis or membranous lupus nephritis (WHO class III, IV, or V) and preserved renal function. However, the duration of follow-up in these trials was not as long as the trials that were conducted to establish the efficacy of cyclophosphamide-based regimens. The ability of mycophenolate mofetil to sustain the remission long term is still unclear (Fig. 56-7).

CHRONIC MAINTENANCE TREATMENT

Steroids and Cytotoxic Agents

Oral steroid is most frequently used for maintenance treatment (prednisolone 5 to 15 mg/day or equivalent). Alternate-day regimens, although not evaluated, are often used in children to minimize growth retardation. Monthly pulse IV steroids in conjunction with cyclophosphamide resulted in more sustained remission, fewer relapses, and no significant increase in side effects. Meta-analysis shows this combination to be more beneficial than steroid or cyclophosphamide alone. Cyclophosphamide, because of its bladder and gonadal toxicity, has been given as monthly and then bimonthly intravenous injection, instead of daily administration, for 2 or more years. However, toxicity is still a concern. A study conducted in Europe showed that after initial lower pulse doses of IV cyclophosphamide, oral azathioprine was able to attain remission rates similar to those of higher initial pulse doses of cyclophosphamide with quarterly follow-up doses. Recently, daily doses of mycophenolate mofetil or azathioprine for 2 years have been shown to be more effective than intravenous pulses of cyclophosphamide in reducing relapse while being less toxic.

Cyclosporine

Cyclosporine may reduce proteinuria and lupus activity, stabilize renal function, and improve kidney morphology. It has been shown to have comparable efficacy and safety with azathioprine in preventing relapse for patients with diffuse proliferative lupus nephritis.

ALTERNATIVE THERAPEUTIC AGENTS

Many new agents have been developed to target the various pathways, costimulatory molecules, and immune mediators responsible for the pathologic autoantibody production.

LJP-394 (Riquent, abetimus sodium), composed of four double-stranded oligodeoxynucleotides, render specific B lymphocytes unresponsive to immunogen by cross-linking with the surface immunoglobulin receptors, thereby reducing anti-DNA antibody production. It may reduce renal and systemic SLE flares in a subgroup of patients whose anti-DNA antibodies are bound avidly to the compound. However, a subsequent study did not reveal such a beneficial effect when compared with placebo. Rituximab is a monoclonal antibody directed against CD20, which is a membrane-associated glycoprotein on B lymphocytes. It causes B-lymphocyte depletion without affecting plasma cells, which do not have CD20. For patients, the B-cell depletion correlates with clinical response. The drug has been reported to have 75% response rate in refractory lupus or lupus nephritis. However, these studies are uncontrolled, and different regimens were used in heterogeneous groups of patients. In the first randomized trial rituximab failed to show a superior response for patients receiving glucocorticoids and other background immunosuppressant therapy for remission induction in moderately to severely active nonrenal
lupus. Results from ongoing randomized trials are needed to confirm its efficacy. Studies are also under way to evaluate epratuzumab (anti-CD22).

Disruption of communication between B and T cells can result in reduced autoimmune response. Different anti-CD40 ligand monoclonal antibodies, such as BG9588 (rulizumab) and IDEC-131, have been evaluated; however, they were not found to be useful because of life-threatening thromboembolic complications.

**TREATMENT OUTCOME**

The prognosis of patients with class II disease is generally good, and often no specific treatment is needed. For patients with class V disease, steroids alone commonly induce partial or complete remission. Immunosuppressive agents can be used for those who are not responsive to steroids. The survival of patients with classes III and IV disease has improved during the last two to three decades to approximately 74% to 80% at 10 years. With the recent use of mycophenolate mofetil, better understanding of the optimal cytotoxic regimens, the use of lower steroid dosages, and better management of complications such as hypertension, infections, hyperlipidemia, and other metabolic complications of the disease, the long-term outcome has become more favorable. Lupus patients with end-stage kidney disease on dialysis fare as well as those with non-lupus–related renal disease. In those patients who received a renal transplant, the allograft outcome of patients with lupus nephritis is favorable and comparable to those without lupus. Recurrence of lupus in the renal allograft can occur but is usually of minor clinical importance.

**RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS**

**Etiology and Epidemiology**

Rapidly progressive glomerulonephritis (RPGN) describes a clinicopathologic syndrome of rapid loss of renal function—usually a greater than 50% decrement of the GFR within 3 months. The predominant histologic finding of RPGN is extensive crescent formation, usually in more than 50% of the glomeruli. Hence, it is also known as crescentic glomerulonephritis. RPGN accounts for 2% to 7% of all renal biopsy findings and is responsible for up to 5% of patients with end-stage kidney disease. The age ranges of susceptible patients vary with the type of RPGN. For example, types I and II RPGN are more common in younger patients, whereas type III is seen more frequently in older individuals.

RPGN is not a single disease entity. A variety of glomerulonephritides with or without systemic diseases may present as RPGN, including anti-GBM glomerulonephritis, Goodpasture syndrome, lupus nephritis, poststreptococcal glomerulonephritis, membranoproliferative glomerulonephritis, IgA nephropathy, polyarteritis nodosa, Wegener granulomatosis, and idiopathic crescentic glomerulonephritis.

Primary RPGN is categorized according to the immunofluorescence microscopic findings, indicating different immunopathogenesis, therapeutic approaches, and clinical outcome. Type I is characterized by the linear localization of immunoglobulins, mainly IgG, along the GBM, signifying anti-GBM antibody-induced injury. Type II is defined by the coarse granular deposition of immunoglobulins and complement within the capillary walls and mesangium, indicating immune-complex–mediated injury. Type III is characterized by scanty or complete lack of immune complex deposits; consequently, it is also known as pauci-immune RPGN. Circulating ANCA are often detected in type III RPGN.

**Pathophysiology**

Different etiologic factors are implicated as the cause of RPGN: toxins, drugs, viral and bacterial infections, neoplasms, autoimmune mechanisms, and various immunogenetic factors. Regardless of the etiology and type of RPGN, damage in the glomerular capillary wall by both humoral and cellular pathways of inflammation is common. Activation of the terminal C5b-9 (membrane-attacking complex) of the complement system produces severe capillary wall injury. Proteinases and reactive oxygen species released by neutrophils and macrophages may result in severe glomerular injury. Platelets and the coagulation system are activated and result in capillary thrombosis. The ruptured capillaries release fibrinogen and procoagulants that may come into contact with thrombogenic tissue debris and lead to fibrinoid changes. In anti-GBM glomerulonephritis, the direct attack of the anti-GBM antibody on the GBM is responsible for the capillary wall injury. For patients with ANCA-associated disease, the interaction of ANCA with neutrophils and monocytes, which have been primed by concurrent infections or inflammatory processes, can lead to activation of these leukocytes and release of toxic oxygen species and lytic enzymes, resulting in vascular injury.

The disruption of the capillary wall allows movement of macrophages and other plasma constituents into Bowman space and stimulates the formation of crescents, which are composed mainly of parietal epithelial cells, as well as macrophages and fibroblasts. Crescent formation indicates the severity of the glomerular capillary disease but not its pathogenesis.

**Clinical Presentation**

Among the crescentic glomerulonephritides, the pauci-immune RPGN (type III) is the most frequent, accounting for more than 50% of cases, whereas the anti-GBM antibody-mediated RPGN (type I) is the least frequent, occurring in roughly 10% to 20% of patients. Of patients with type I RPGN, 60% to 70% may have concurrent pulmonary hemorrhage and Goodpasture syndrome, which is caused by antibodies directed against the pulmonary alveolar basement membrane. Most patients with immune-complex–mediated RPGN (type II) have collagen vascular disease, systemic infections, or a severe form of primary glomerular disease. Approximately 70% of patients with type III RPGN also present with evidence of systemic vasculitis, such as Wegener granulomatosis and polyarteritis nodosa. Some patients have only renal manifestations and are said to have idiopathic crescentic glomerulonephritis or renal vasculitis.

The clinical presentation is dominated by progressive renal insufficiency with complaints of tea-colored urine, malaise, anorexia, low-grade fever, and migratory polyarthropathy. Type I RPGN is more common in younger patients, whereas patients with ANCA-mediated disease tend to be older. Urinalysis commonly shows nephritic sediments with hematuria, erythrocyte casts, and proteinuria. However, overt nephrotic syndrome is rare.

Serologic analysis is very useful in distinguishing the different types of RPGN. The detection of serum anti-GBM antibodies with the appropriate clinical presentation confirms the diagnosis of anti-GBM glomerulonephritis. More than 80% of patients with pauci-immune or idiopathic crescentic glomerulonephritis have circulating ANCA. ANCA are autoantibodies specific for the cytoplasmic constituents of neutrophil granules and monocyte lysosomes. Patients with ANCA-associated disease limited to renal involvement often have P-ANCA (perinuclear staining), whereas patients with Wegener granulomatosis tend to have C-ANCA (cytoplasmic staining). Both the anti-GBM antibody and the ANCA are absent in patients with type II RPGN. Measurements of circulating immune complexes are not useful for making a specific diagnosis, but detection of specific serum antibodies known
to mediate immune complex–associated nephritis is helpful, using anti-DNA antibody as a marker for lupus nephritis and elevated antistreptolysin O titers for poststreptococcal glomerulonephritis.

**TREATMENT**

### Rapidly Progressive Glomerulonephritis

Early aggressive therapy has improved the renal prognosis of patients with crescentic glomerulonephritis. The rapid deterioration of renal function and the paucity of a large number of patients make randomized controlled studies very difficult to conduct. Based on the available data, immunosuppressive therapy alone appears to be ineffective for type I RPGN, while types II and III RPGN respond well to high-dose steroid therapy. Regardless of the type of RPGN, poor response to therapy and an ominous renal survival are expected if the patient presents with oliguria, has a serum creatinine concentration greater than 6 or 7 mg/dL (530 or 619 μmol/L), is dialysis dependent, or has a renal biopsy showing advanced chronic parenchymal disease. Because of the differences in response, the therapeutic approaches for each type of RPGN are presented separately below.

### ANTIGLOMERULAR BASEMENT MEMBRANE GLomerulonephritis (TYPE I)

Steroids and cyclophosphamide, in conjunction with plasma exchange, have been used effectively to control the disease. Plasma exchanges remove the pathogenic anti-GBM antibodies in circulation and are conducted for 2 weeks or until the antibodies disappear. Steroids (prednisolone 1 mg/day, tapered over 6 months) and cyclophosphamide (2 to 3 mg/kg/day for 3 months) are then given to prevent new antibody production. Patients with mild disease generally respond well to plasma exchange alone or immunosuppression (steroid and/or cytotoxic agents). For patients with severe disease (poor renal function and extensive crescent formation), most are expected to respond to the combination of plasma exchange and steroid/cytotoxic drug therapy. Pulse intravenous administration of corticosteroids (methylprednisolone 30 mg/kg/day for 3 days) has been used successfully to alleviate pulmonary hemorrhage, but the results are not as convincing for glomerulonephritis. Because of the rapid decline in renal function, diagnosis should be established early so that therapy can proceed without delay. When the serum creatinine concentration is 6 mg/dL (530 μmol/L) or above or the patient is oliguric or requires dialysis, the response to therapy is usually poor, and the patient should be treated conservatively. Poor response should also be expected when crescents are found in more than 85% of the glomeruli.

### IMMUNE-COMPLEX–MEDIATED GLOMERULONEPHRITIS (TYPE II)

Patients with postinfectious RPGN generally have a favorable prognosis even without treatment. Complete spontaneous recovery occurs in 50% of cases, whereas chronic renal failure develops in 32%. Pulse doses of methylprednisolone (30 mg/kg/day, every other day × 3), followed by oral prednisone (1 mg/kg/day, tapered over several months) and then tapering, are beneficial in type II RPGN, with a response rate of 85% for patients with acute disease and 70% in those with more chronic disease. Plasmapheresis does not appear to provide any additional benefit.

### ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY-ASSOCIATED GLOMERULONEPHRITIS (TYPE III)

Combined use of high-dose corticosteroids and cyclophosphamide induces remission in more than 90% of patients. Cyclophosphamide, if given intravenously, is associated with fewer infectious complications while being as effective as the oral route in inducing remission; however, the risk of relapse may be higher. Because approximately 30% of the patients may relapse, cyclophosphamide also has been used for maintenance therapy. Mycophenolate mofetil and methotrexate are now being used, and they have been shown in limited studies to be effective. Plasmapheresis is not expected to have any additional benefits for patients with mild to moderate disease who are receiving immunosuppressive therapy. However, as an adjunct to immunosuppressive therapy, it may be beneficial for patients with severe disease presenting with acute renal failure, especially those with pulmonary hemorrhage.

### RENAL TRANSPLANTATION

Anti-GBM nephritis may recur in up to 55% of patients who received a renal transplant. However, only 25% of these patients showed clinical disease activity, with rare allograft failure. Because the frequency of recurrence and its severity are related to the presence of circulating anti-GBM antibody, it is recommended that transplantation should not be performed until the anti-GBM antibody is undetectable for at least 6 to 12 months. The recurrence rate of ANCA-associated nephritis is 17%, with the average time to relapse from transplantation of 31 months.

### POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

#### Etiology and Epidemiology

Poststreptococcal glomerulonephritis (PSGN) and glomerulonephritis caused by other infectious agents, such as bacteria, viruses, and parasites, were once common. Improved sanitation, personal hygiene, medical care, and public health measures helped to decrease the incidence of group A streptococcal infection both in the United States and in other developed countries, resulting in a decline of PSGN. In contrast, glomerulonephritis secondary to other infectious agents, such as hepatitis C and HIV, is seen with increasing frequency.

PSGN is now the most common form of glomerulonephritis in children but is less common than the other types of glomerulonephritis in adults. PSGN is seen mostly in children aged between 5 and 15 years and is uncommon in children younger than 2 years of age and in adults older than 50 years of age. It normally follows pharyngitis or skin infection caused by the nephritogenic strains of group A streptococci; however, other strains of streptococci, such as groups C and G, have also been reported to cause PSGN. Streptococcal pharyngitis is more common in winter and early spring, whereas skin infection is frequently found in the summer. The risk for developing acute glomerulonephritis secondary to the nephritogenic strains of bacteria is approximately 10% to 15% for infected patients. However, three to four times more patients may experience a subclinical form of the disease.

#### Pathophysiology

Streptococcal antigens may induce changes in the glomerular components rendering them immunogenic or autologous IgM may be altered to become antigenic. Alternately, the streptococcal antigens may induce antibodies that react with glomerular antigens. In situ
immune complexes are then formed and result in a complement-mediated inflammatory response. The kinin and coagulation cascades are activated, and chemotactic factors are released to recruit neutrophils and monocytes, resulting in acute glomerular lesions.

Examination of the acute PSGN kidneys reveals hypercellular glomeruli with proliferation of mesangial and endothelial cells. Infiltration of neutrophils, monocytes, and eosinophils is apparent within the capillary lumen and also in the mesangial areas. Crescent formation may be seen for patients with severe disease, and if found in more than 30% of the glomeruli, RPGN may be present concurrently. The prognosis is generally poor for these patients, and complete recovery is unlikely. Immunofluorescence examination reveals diffuse granular deposits of IgG and C3 along the GBM and also in the mesangium.

**Clinical Presentation**

The nephritis is preceded by a latent period following a streptococcal infection. The latent period is commonly 7 to 14 days for pharyngitis and 14 to 28 days for skin infection. An acute nephritic syndrome then develops, commonly with hematuria and edema. Gross hematuria is seen in 70% of patients, and microscopic hematuria can be found in all patients. Hypertension is usually mild to moderate and results from sodium and water retention. Many patients have signs and symptoms associated with volume overload, which include dyspnea, orthopnea, and cough. Urinalysis of patients with PSGN reveals hematuria, dysmorphic red blood cells, and red cell casts. Proteinuria is common but often not in the nephrotic range. Renal function is frequently mildly impaired.

Throat or skin culture may be positive for group A streptococci, despite the latent period following the initial infection. However, antibiotic therapy may render the culture result negative. Serologic measurements of antibodies to different streptococcal antigens can confirm recent exposure to the infection. Titers that can be measured include antistreptolysin O (ASO), antistreptokinase, antihyaluronidase (AHase), antideoxyribonuclease B (ADNase B), and antinicotyladenine dinitroelectidase (NADase). For most patients with streptococcal pharyngitis, the ASO titers begin to rise about 10 to 14 days later, peak at 3 to 4 weeks, and persist for several months before decreasing. The rise in ASO titers can be reduced by antibiotic treatment and may not be seen for patients with streptococcal skin infection in whom the streptolysin may be bound to skin lipids. ADNase B and AHase titers should be used instead because they are specific and are positive in the majority of patients. The streptozyme test is a combined assay for ASO, ADNase B, NADase, and AHase. Antibodies to other antigens such as zymogen, streptococcal cationic proteinase exotoxin B (SPEB), and plasmin receptor (Pr) were evaluated recently.

Serum complement levels are often decreased for patients with PSGN. If the C3 level is depressed for more than 6 to 8 weeks, MPGN, lupus nephritis, or glomerulonephritis related to endocarditis or occult visceral abscess should be suspected. Renal biopsy is not normally indicated unless the patient has prolonged hematuria, proteinuria, or depressed C3 level. Renal biopsy is needed to detect other types of glomerulonephritis such as lupus, RPGN, or MPGN.

**TREATMENT**

### Poststreptococcal Glomerulonephritis

The treatment of PSGN is mainly supportive and symptomatic. Early antibiotic therapy does not prevent subsequent PSGN, but it may reduce the severity of the disease. It can, however, prevent the spread of the streptococcal infection to other family members. Antibiotic prophylaxis is not recommended because infected patients will develop long-lasting, often lifelong immunity against the strain of streptococci. Exposure to another nephritogenic strain of streptococci is possible, but unlikely.

Supportive measures should be used to control fluid volume and blood pressure. Because the hypertension is of the low-renin type, ACEIs and β-blockers are not expected to be useful. If the patient has crescentic disease, use of pulse steroids and/or immunosuppressive agents can be considered; however, the efficacy and safety of these agents have not been established for this condition.

The acute manifestations of PSGN are normally self-limited, and for more than 95% of patients renal function has returned to baseline within 3 to 6 weeks. Diuresis usually begins 7 to 10 days after onset of the acute episode, whereas hypertension and azotemia resolve in 1 to 2 weeks. Gross hematuria lasts for 1 to 2 weeks, and proteinuria usually resolves within 6 months in more than 90% of children. However, microscopic hematuria may persist for up to 2 years. In general, children have more rapid recovery than adults. Prognosis is often better when PSGN occurs during an epidemic than in cases found sporadically. Most of the children will recover fully and be free from chronic complications of PSGN if they have no preexisting renal disorder, heavy proteinuria, or crescentic glomerular lesions or did not require hospitalization during the acute episode. In contrast, adult patients have a less favorable long-term outcome. As many as 50% of the patients may develop persistent proteinuria, hypertension, and renal insufficiency, with some resulting in end-stage renal failure.

**PHARMACOECONOMIC CONSIDERATIONS**

Prospective, randomized, controlled comparative trials need to be conducted in a sizable patient population before the efficacy and economic implications of a new regimen can be established. This type of large-scale study is potentially feasible for the more common forms of glomerulonephritis, such as minimal-change disease, IgA nephropathy, and membranous nephropathy. In contrast, prospective controlled trials are difficult to conduct for the relatively uncommon glomerulonephritides such as membranous proliferative glomerulonephritis. After defining the natural history and the optimal drug regimen for each glomerulonephritis, in conjunction with the incidence of drug-induced complications, the economic implications of the individual treatment approach can be assessed. However, the optimal approaches for treating most types of glomerulonephritis have not been identified, and the economic implications of the individual treatment regimens thus remain to be established.

**CONCLUSIONS**

A better understanding of the pathogenetic mechanisms leading to glomerular injury has improved the treatment of glomerulonephritis. However, the glomerulopathies are a heterogeneous group of immune disorders with different clinical courses, prognoses, and responses to current immunologic and non-immunologic therapies. The clinician should understand the natural history and prognosis of each subgroup of glomerulonephritis, the efficacy of different immunomodulation regimens in inducing disease remission and preserving renal function, and the characteristics of at-risk patients who warrant aggressive therapy. Judicious use of immunosuppressive agents with careful monitoring of their adverse effects cannot be overemphasized.
In addition, treatment of the disease complications and control of factors that lead to progression of renal disease are important in reducing the morbidity and mortality of patients with glomerulonephritis.

ABBREVIATIONS

ACE: angiotensin-converting enzyme
ADNase B: antidiuretic hormone B
AHase: antihyaluronidase
ANCA: antineutrophil cytoplasmic autoantibody
ARB: angiotensin II receptor blocker
ASO: antistreptolysin O
ESRD: end-stage renal disease
GBM: glomerular basement membrane
GFR: glomerular filtration rate
FSGS: focal segmental glomerulosclerosis
HIV: human immunodeficiency virus
HMG-CoA: hydroxymethylglutaryl coenzyme A (reductase)
IL: interleukin
LDL: low-density lipoprotein (cholesterol)
MPGN: membranoproliferative glomerulonephritis
NADase: anticentromere antibody
PSG: poststreptococcal glomerulonephritis
RPGN: rapidly progressive glomerulonephritis
SLE: systemic lupus erythematosus
VLDL: very-low-density lipoprotein (cholesterol)

Drug Therapy Individualization for Patients with Chronic Kidney Disease

GARY R. MATZKE

KEY CONCEPTS

1. Chronic kidney disease has been demonstrated to result in minimal alterations in the absorption or bioavailability of only a few drugs.

2. The volume of distribution of many drugs is increased in the presence of acute and chronic kidney disease (CKD) as a consequence of volume expansion and reduced protein binding.

3. In addition to the expected decrement in renal clearance, nonrenal clearance (i.e., gastrointestinal and hepatic drug metabolism) of several drugs is also reduced in patients with CKD.

4. Individualization of a drug dosage regimen for a patient with reduced kidney function is based on the pharmacodynamic/pharmacokinetic characteristics of the drug and the patient’s degree of residual renal function.

5. The drug dosing guidelines for patients with CKD in many drug information resources are highly variable and thus many are not optimal for clinical use.

6. The effect of hemodialysis or peritoneal dialysis on drug elimination is dependent on the characteristics of the drug and the dialysis prescription.

7. The application of hemodialysis clearance data to guide drug dosage regimen design for hemodialysis patients is limited and prospective monitoring of serum concentrations is often warranted.

Patients with chronic kidney disease (CKD) are commonly encountered in clinical practice. Indeed, it is estimated that nearly 15 million adults in the United States have serum creatinine values of 1.5 mg/dL (133 mmol/L) or greater. In older adults, age-related declines in renal function combine with an increased use of medications to make this patient group particularly susceptible to adverse effects secondary to the lack of appropriate pharmacotherapy individualization.

The presence of a marked reduction in kidney function, whether it is an acute kidney injury (AKI) or CKD in any patient, necessitates that the clinician individualize drug therapy to maximize therapeutic outcomes.

CKD is often accompanied by the development of anemia, hyperparathyroidism, hyperlipidemia, hypertension, and changes in gastrointestinal tract integrity (see Chapters 52 and 53). Thus CKD patients are often prescribed an extensive array of medications. There are now many reports that document changes in the disposition of some drugs in patients with CKD as the result of changes in bioavailability, distribution volume, and metabolic activity. Thus drug therapy individualization is warranted for most patients with CKD. If a drug is predominantly renally eliminated unchanged, a dosage regimen adjustment may be calculated on the basis of the ratio of the patient’s residual renal function relative to an age and gender normal value for estimated creatinine clearance or glomerular filtration rate. However, for medications that are extensively metabolized or for which dramatic changes in protein binding and/or distribution volume have been noted, a more complex adjustment strategy may need to be employed.

Furthermore, because of the physiologic and biochemical changes associated with progressive CKD, patients may respond to a given dose or serum concentration of a drug differently than patients with normal renal function.

Clinicians thus design individualized therapeutic regimens to optimize therapeutic outcomes and minimize adverse events, if they use basic pharmacokinetic principles combined with the drug’s disposition properties and the patient’s clinical characteristics. In this chapter, the influence of CKD on drug absorption, distribution, metabolism, and elimination is characterized. The array of drug information resources for the adjustment of the dosage regimens for patients with CKD is critiqued. A practical framework for drug dosage individualization for patients with CKD based on continuous versus categorical classifications is presented and the influences of peritoneal dialysis and hemodialysis on drug disposition are discussed. Finally, drug administration strategies for those receiving hemodialysis are presented. Drug dosage regimen adjustment strategies for patients with AKI, including those who are receiving continuous renal replacement therapy are presented in Chapter 51.

EFFECT ON DRUG ABSORPTION

1. There is little quantitative information regarding the influence of CKD on drug absorption and bioavailability. Changes in gastrointestinal transit time and gastric pH, edema of the gastrointestinal tract, vomiting and diarrhea (frequent complications of severe renal insufficiency), and antacid administration have all been proposed as a rationale for alterations in the bioavailability of drugs in CKD patients. Evaluations of bioavailability are generally conducted in those with severe stable renal insufficiency, that is, stage 5 CKD, which is also called end-stage renal disease (ESRD). The assessment of bioavailability in this patient population is,
however, complicated, because most of these patients are prescribed multiple medications (often in excess of 10 to 12 different agents), many of which cannot be discontinued during the course of a bioavailability study.

Many of the drug absorption so-called “bioavailability” studies in ESRD patients were not designed to provide an assessment of the drug’s absolute bioavailability (i.e., they did not include a comparison of oral to intravenous administration of the drug). Rather, the principal outcomes were the documentation of alterations in the peak concentration (Cmax) time at which the peak concentration was attained (tmax), or in the fractional amount of drug recovered in the urine in a finite time period. Unfortunately, this limited information has been extrapolated by some into a general conclusion that drug absorption is slowed and/or that the extent of absorption is reduced as the result of the development of CKD.5

In fact, the absolute bioavailability of only a few drugs is affected by ESRD and many of these are rarely used.47 An increase in bioavailability as the result of a decrease in metabolism during the drug’s first pass through the gastrointestinal tract and liver has been noted for some β-blockers (e.g., bufarolol, oprenolol, propranolol, and tolamolol), dextropropoxyphene, and dihydrocodeine.48 Although the bioavailability of these compounds is increased, clinical consequences (development of excessive or unexpected adverse effects) have only been demonstrated with dextropropoxyphene and dihydrocodeine.

**EFFECT ON DRUG DISTRIBUTION**

The volume of distribution of many drugs is increased in patients with moderate to severe CKD as well as those with preexisting CKD who develop AKI (Table 57−1).2415 This increase in distribution volume may be the result of decreased protein binding, increased tissue binding, or pathophysiologic alterations in body composition (e.g., fluid overload).

Generally, the plasma protein binding of acidic drugs (e.g., warfarin and phenytoin) is decreased in those with ESRD,79,16 whereas the binding of basic drugs (e.g., quinidine and lidocaine) is usually normal or only slightly decreased or increased (Table 57−2).5,6 The decrease in binding of acidic drugs has been attributed to qualitative changes in the binding sites, accumulation of endogenous inhibitors of binding, and/or decreased concentrations of albumin. The first two of these mechanisms appear to account for most of the observed changes in binding. In addition, the high concentrations of metabolites of some compounds that accumulate in patients with ESRD may compete for protein binding sites with the parent compound.

The unbound fraction of many acidic drugs increases in CKD patients as the result of a decrease in protein binding. A new equilibrium is ultimately established as a result of increased drug elimination/distribution, such that the unbound concentrations remain comparable to those observed in patients with normal renal function despite the fact that total concentrations are reduced. Thus, the net effect is an alteration in the relationship between total drug concentration and pharmacodynamic effect; it is commonly seen with the anticonvulsant phenytoin. The protein binding of this acidic drug, which binds to albumin, is significantly reduced and this change alters the relationship between total phenytoin concentration and desired effect as well as toxicity.17 The resulting increase in unbound fraction, from values of 10% in those with normal renal function to ~20% or more in those with stage 5 CKD, results in increased hepatic clearance and decreased total concentrations. Thus, in patients with CKD, the therapeutic range based on total

phenytoin concentration is shifted downward from normal values of 10 to 20 mg/L (10–20 mcg/mL; 40–79 mmol/L) to values as low as 4 to 8 mg/L (4–8 mcg/mL; 16–32 mmol/L). Since the unbound concentration therapeutic range is the same for all patients, 1 to 2 mg/L (1–2 mcg/mL; 4–8 mmol/L), such a measurement provides the best target for individualizing phenytoin therapy in patients with CKD.

When unbound concentration measurements are not clinically available, one can approximate the equivalent “total” phenytoin concentration in an ESRD patient relative to an individual with normal renal function.17 Although these approaches have not been rigorously evaluated, they may be useful in some clinical settings to predict dosage requirements.

The principal binding protein for several basic drugs is α1-acid glycoprotein, an acute-phase reactant protein whose plasma concentrations are increased in CKD patients.3–7 As a result of this increase, the unbound fraction of some basic drugs may be significantly decreased in ESRD patients.

Altered tissue binding may also affect the apparent volume of distribution of a drug. For example, the distribution volume of digoxin has been reported to be reduced by 30% to 50% from normal values in patients with stage 5 CKD, as well as in hemodialysis patients.2 This reduction in the distribution volume may be secondary to a decrease in tissue binding as a result of competitive inhibition by endogenous or exogenous substances. Acidosis or the presence of digoxin-like immunoreactive substances that bind to and inhibit membrane adenosine triphosphatase may also contribute to this phenomenon.19 In this situation, the absolute amount of digoxin bound to the receptor is reduced and the resultant serum digoxin concentration is higher than anticipated. Multiple methods have been proposed to estimate the degree of reduction in digoxin’s distribution volume.18

Thus, in patients with renal insufficiency, particularly in those with stage 5 CKD, a “normal” total drug concentration may be associated with either an adverse reaction secondary to elevated unbound drug concentrations, or a subtherapeutic response because of an altered plasma-to-tissue drug concentration ratio. The monitoring of unbound drug concentrations in CKD patients is thus warranted for those drugs that have a narrow therapeutic range, are highly protein bound (free fraction of <20%), and for which marked variability in the free fraction has been reported (e.g., phenytoin and disopyramide).

Finally, the method used to calculate the volume of distribution may be influenced by renal insufficiency. The three most commonly used volume of distribution terms are: volume of the central compartment \( V_c \), volume of the terminal phase \( V_e \) and \( V_{\text{meas}} \), and volume of distribution at steady state \( V_s \). The \( V_{\text{meas}} \) for many drugs approximates extracellular fluid volume and thus may be increased or decreased by acute changes. Oliguric acute renal failure is often accompanied by fluid overload and a resultant increased \( V_e \) for many drugs. The \( V_{\text{meas}} \) or \( V_s \) represents the proportionality constant between plasma concentrations in the terminal elimination phase and the amount of drug remaining in the body. \( V_c \) is affected by both distribution characteristics, as well as by the terminal elimination rate constant. \( V_e \) and \( V_s \) will often be similar in magnitude, with \( V_c \) being slightly larger. Because \( V_{\text{meas}} \) has the advantage of being independent of drug elimination, it is the most appropriate volume term to use when one desires to compare drug distribution volumes between patients with renal insufficiency and those with normal renal function.21

**EFFECT ON METABOLISM**

A decrease in the renal clearance of drugs in patients with CKD is well appreciated. However, there is now good preclinical and emerging clinical evidence that CKD may lead to alterations in nonrenal clearance of many medications as the result of alterations in the activities of uptake and efflux transporters as well as cytochrome P450 (CYP) enzymes in the liver and other organs8–11,22,23 (Table 57-3). However, the effect(s) of renal insufficiency on nonrenal drug clearance also appears to depend on whether the reduction in renal function is acute or chronic in nature. The degree of reduction in those with AKI does not appear to be as great as that observed in ESRD patients.14

Although the early studies should be interpreted with caution because concurrent drug intake, age, smoking status, and alcohol intake were often not well controlled, those published in the last few years provide strong evidence of a significant independent effect of CKD on drug metabolism, predominantly for those drugs which are metabolized by CYP3A4 (Table 57-4). CYP3A4 activity as measured by the erythromycin breath test (EBT) is 28% lower in ESRD patients as compared with healthy controls.24 Although baseline CYP3A4 activity was lower in these patients, the increase in CYP3A activity observed following enzyme induction with rifampin was similar.24 Nolin and colleagues have recently shown that EBT results are reduced more in those ESRD patients with higher blood urea nitrogen concentrations and that hemodialysis is associated with an acute improvement in the patient’s metabolic activity.7 These data indicate that CKD has a detrimental effect on this important pathway of hepatic drug metabolism in humans.

Prediction of the effect of renal insufficiency on the metabolism of a particular drug is however difficult and there is currently no quantitative strategy to predict changes for one drug based on data from another in the same class. However, some qualitative insight can be gained if one knows what enzyme is involved in the metabolism of the drug of interest and how the enzyme(s) or transporter(s) is affected by the presence of CKD.

Investigations of the effect of chronic renal failure on hepatic enzyme activity in animals have demonstrated reductions in some, but not all, pathways of drug metabolism.2,22,21 The mechanism(s) by which CKD affects hepatic drug metabolism is not clearly known, but may relate to accumulation of endogenous inhibitors (e.g., uremic toxins) or to the fact that CKD patients exist in a chronic inflammatory state and have increased levels of oxidative stress,25 and other factors known to downregulate CYP enzymes.26 In rat models of chronic renal failure, protein expression of several CYP enzymes, including CYP3A1 and CYP3A2 (corresponding to human CYP3A4), is reduced in the liver by as much as 75%. The mechanism of this decrease in protein content and messenger ribonucleic acid
expression suggests transcriptionally mediated downregulation or post-translational inhibition of the metabolic pathway.322

Thus, current data suggest a differential effect on the individual CYP enzymes with the activity of some enzymes (e.g., CYP3A4 and CYP2C9) being reduced, while others (e.g., CYP2E1) are not affected.324 This differential effect on individual enzymes may help to explain some of the conflicting reports of whether drug metabolism is altered in the presence of CKD.

**EFFECT OF RENAL INSUFFICIENCY ON METABOLITE ELIMINATION**

Patients with severe renal insufficiency who are receiving chronic treatment with some agents may experience accumulation of metabolite(s) as well as parent compound. Metabolites of several drugs have been reported to have significant pharmacologic and/or toxicologic activity. However, the pharmacokinetics and pharmacodynamics of metabolites are not often fully elucidated. In a sense, the patient with severe CKD is being exposed to a new pharmacologic entity since the sum of the serum concentrations of the metabolite and the parent compound are markedly different than those reported in patients with normal renal function.

The metabolite may have pharmacologic activity similar to that of the parent drug and thus contribute significantly to clinical response; that is true, for example, of oxypurinol. Alternatively, the metabolite may have qualitatively dissimilar pharmacologic action; for example, normeperidine has central nervous system (CNS) stimulatory activity that reportedly produces seizures, whereas meperidine has CNS depressant actions.27 Because of the multiplicity of potential interactions of compounds that are primarily metabolized, the practical consequences of metabolite accumulation are difficult to predict and are most often identified in those patients at risk by trial and error.

**EFFECT OF CKD ON RENAL DRUG EXCRETION**

Renal clearance (Cl) of a drug is the composite of GFR, tubular secretion, and reabsorption ([Cl, = (GFR × f) + (Clsecretion + Clreabsorption)], where f is the fraction of the drug unbound to plasma proteins. Drug elimination by filtration occurs by diffusion; while tubular secretion and reabsorption are bidirectional processes that involve carrier-mediated renal transport systems.28 Renal transport systems have been broadly classified on the basis of substrate selectivity into the anionic and cationic renal transport systems, which are responsible for the transport of a number of organic acidic and basic drugs, respectively (see Chapter 50). Renal organic anion transport is mediated by transporters, transporting polypeptides, and multidrug resistance-associated protein transporters.29 Several drugs, including β-lactam antibiotics, diuretics, and nonsteroidal antiinflammatory drugs, are actively secreted by one or more of these transporter families which also have an essential role in the elimination of glucuronide metabolites. Organic cation transport systems mediate the reabsorption and excretion of endogenous cationic compounds and drugs (e.g., cimetidine, famotidine, and quinidine). The P-glycoprotein transport system in the kidney is also involved in the secretion of cationic and hydrophobic drugs (e.g., digoxin and vinca alkaloids).30 Other important renal transport systems include the peptide transporters, which are involved in the uptake of peptide-like drugs including β-lactam antibiotics and angiotensin-converting enzyme inhibitors, while nucleoside transporter proteins are involved in uptake of nucleosides and nucleoside analogs (e.g., zidovudine and didoxycyoxinosine).

Alterations in filtration, secretion, or reabsorption, secondary to CKD may have a dramatic effect on drug disposition; for drugs that are primarily filtered, a reduction in glomerular filtration rate will result in a proportional decrease in renal drug clearance. However, for drugs that are extensively renally secreted (Cl, > 300 mL/min [≥ 5.00 mL/s]), the loss of filtration clearance (up to 120 mL/min [2.00 mL/s]) will have less of an impact. In the absence of data delineating the contribution of tubular function to renal clearance, the clinical measurement or estimation of creatinine clearance remains the guiding factor for drug dosage regimen design.312 The importance of an alteration in renal function on drug elimination depends on two factors: the fraction of drug normally eliminated by the kidney unchanged and the degree of renal insufficiency. Quantitation of the patient’s renal function can be accomplished by measurement of Clcr or GFR or estimation of Clcr or GFR based on the stable serum creatinine concentration (see Chapter 50). Because of the time delay involved and problems in obtaining complete urine collections, measured Clcr or GFR values are infrequently used for initial drug dosage regimen design. Therefore the calculation of initial drug dosage regimens relies on the estimation of Clcr or GFR in adults and children from such routinely available clinical data as age, gender, height, weight, and serum creatinine. Although several methods have been proposed to estimate GFR from routinely available clinical data (see Chapter 50) the usefulness of an estimated GFR (eGFR) to guide drug dosing has only recently been extensively evaluated.30–33 The results of these investigations have yielded controversial findings and future prospective studies of the relationship between estimated Clcr and GFR and the total body clearance of medications will likely be needed to resolve this issue. At the present time the use of Clcr is preferred but the use of eGFR is likely better than not

<sup>a</sup> Clearance in mL/min can be converted to mL/s through multiplication by 0.0167.

### DRUG DOSAGE REGIMEN DESIGN FOR PATIENTS WITH CHRONIC KIDNEY DISEASE

An approach for designing a dosage regimen for a patient with CKD is depicted in Table 57–5. The design of the optimal dosage regimen is dependent on the availability of an accurate characterization of the relationship between the pharmacokinetic parameters of the drug and renal function and an accurate assessment of the patient’s renal function (CL<sub>T</sub>). Prior to 1998 there was no consensus regarding the explicit criteria for characterization of the relationship between the pharmacokinetics and pharmacodynamics of a drug and renal function. The U.S. Food and Drug Administration (FDA) industry guidance issued in May 1998<sup>36</sup> and the European Medicines Agency guidance of 2004<sup>37</sup> provided a framework to help companies decide when they should conduct such a “characterization” study and proposed explicit recommendations for study design, data analysis, and assessment of the impact of the study results on drug dosing. Thus the quality of data available to clinicians has improved dramatically in the last 10 years. A new draft FDA guidance was proposed in 2010 and characterization of the influence of CKD on the pharmacokinetics and pharmacodynamics of a broader range of medications, including many that are predominantly metabolized, is now recommended. The availability of this critical information for many medications will increase the proportion of patients for whom drug dosage individualization will then be practical.

Most dosage-adjustment guidelines have proposed the use of a fixed dose or interval for patients with broad ranges of renal function that are different from those that are the foundation of the CKD staging scheme (see Chapter 52). Indeed, normal renal function has often been ascribed to anyone who has a CL<sub>T</sub> > 80–90 mL/min (1.34–1.50 mL/s), even though the population normal CL<sub>T</sub> values range from 115 to 125 mL/min/1.73 m<sup>2</sup> (>1.11–1.20 mL/s/m<sup>2</sup>). Mild renal insufficiency encompasses the range of 60 to 89 mL/min (1.00–1.49 mL/s), moderate renal insufficiency the CL<sub>T</sub> range of 30 to 59 mL/min (0.50–0.99 mL/s), while severe renal insufficiency and ESRD often are defined as a CL<sub>T</sub> of 15 to 29 mL/min (0.25–0.49 mL/s) and <15 mL/min (<0.25 mL/s), respectively. Each of these categories encompasses a broad range in renal function, and thus the calculated drug regimen may not be optimal for all patients whose renal function lies within the given category of renal function.

Secondary references, such as the American Hospital Formulary Service Drug Information Service, the British National Formulary,<sup>38</sup> and Drug Prescribing in Renal Failure,<sup>39</sup> are generally touted as excellent sources of information about a drug’s pharmacokinetic characteristics in subjects with normal and impaired renal function. A recent analysis of several of these sources suggests a need for a consistent quantitative approach to drug dosage regimen individualization for those with CKD.<sup>40</sup> The authors concluded that the remarkable variation in recommendations along with the paucity of details of the methods used to generate the dosing advice made these sources of drug information less than optimal for clinical use. None of these sources consistently provide the explicit relationships of the kinetic parameters of interest (total body clearance, elimination rate constant, and distribution volume) with a continuous index of renal function, such as CL<sub>T</sub>. To find this information, one may need to identify the original research study that assessed the drug’s disposition or a comprehensive review article on the class of drugs of interest. This is a time-consuming process that may be difficult to carry out for each drug and patient combination in real time. Ideally, one should be able to identify a relationship between total body clearance (CL) or elimination rate constant (k) with an eGFR or CL<sub>T</sub>, such as those depicted in Table 57–6. This information, along with the patient’s estimated CL<sub>T</sub> or GFR is the foundation upon which one can formulate a therapeutic regimen to attain the desired therapeutic outcome.

If specific literature recommendations and/or the relationship of kinetic parameters to eGFR or CL<sub>T</sub> are not available, then one can estimate the CL or k of the patient with the method of Rowland and Tozer,<sup>32</sup> provided the fraction of the drug that is eliminated renally unchanged (f<sub>r</sub>) in subjects with normal renal function is known.<sup>34</sup>
This approach assumes that the change in CL and k are proportional to CL\textsubscript{cr}, that renal disease does not alter the drug’s metabolism, that the metabolites, if formed, are inactive and nontoxic, that the drug obeys first-order (linear) kinetic principles, and that it is adequately described by a one-compartment model. If these assumptions are true, then the kinetic parameter/dosage-adjustment factor (Q) can be calculated as:

\[ Q = 1 - [f_d(1 - KF)] \]

where KF is the ratio of the patient’s CL\textsubscript{cr} to the assumed normal value of 120 mL/min (equivalent to 2.00 mL/s). Thus for a drug that is 85% eliminated renally unchanged in a patient who has a CL\textsubscript{cr} of 10 mL/min (0.17 mL/s), the Q factor would be:

\[ Q = 1 - [0.85(1 - (10/120))] \]
\[ = 1 - [0.85(0.92)] \]
\[ = 1 - 0.78 \]
\[ = 0.22 \]

The best method for dosage regimen adjustment must then be selected. Specifically, one must determine whether the desired goal is the maintenance of a similar peak, trough, or average steady-state drug concentration. If there is a significant relationship between peak concentration and clinical response\textsuperscript{41} (e.g., aminoglycosides) or toxicity\textsuperscript{42} (e.g., quinidine, phenobarbital, and phenytoin), then attainment of the specific target values is critical. If, however, no specific target values for peak or trough concentrations have been reported (e.g., antihypertensive agents and benzodiazepines), then a regimen goal of attaining the same average steady-state concentration may be appropriate.

Although several methods have been proposed to attain the desired average steady-state concentration profile, the principal choices are to decrease the dose or prolong the dosing interval. If the size of the dose is reduced while the dosing interval remains unchanged, the desired average steady-state concentration will be similar; however, the peak will be lower and the trough higher (Fig. 57-1). Alternatively, if the dosing interval is increased and the dose size remains unchanged, the peak and trough concentrations in the patient with reduced renal function will be similar to those in the patient with normal renal function. This dosage adjustment method is often recommended because it is likely to yield cost savings as a result of a reduction in nursing and pharmacy time, as well as a reduction in the supplies associated with frequent drug administration. Finally, the dose and dosing interval may both need to be changed to allow the administration of a clinically feasible dose (500 mg vs a calculated value of 487 mg) or a practical dosing interval, for example, 12 hours instead of 17 hours.

If the relationship between the pharmacokinetic parameters of the drug and renal function are known, the first step in the process is to estimate the drug disposition parameters in the patient with renal insufficiency. The dosage-adjustment factor (Q) can then be calculated as the ratio of the estimated elimination rate constant or total body clearance of the patient relative to subjects with normal renal function (CL\textsubscript{cr} = 120 mL/min [2.00 mL/s]). This parameter may be used to determine the dose or dosing interval alterations necessary for the patient.

For example, the following relationship between total-body clearance (CL) and creatinine clearance (expressed in conventional units of mL/min) has been reported for ganciclovir:\textsuperscript{43}

\[ CL(\text{mL/min}/1.8 \text{ m}^2) = 1.25(\text{CL}_{\text{cr}}) + 8.57 \]

Thus, for CL for a subject with normal renal function (CL\textsubscript{norm}) would be calculated as:

\[ \text{CL}_{\text{norm}} = [1.25(120)] + 8.57 \]
\[ \text{CL}_{\text{norm}} = 158.6 \text{ mL/min per } 1.8 \text{ m}^2 \]

Clearance (CL\textsubscript{ur}) for a patient with a creatinine clearance of 10 mL/min would be:

\[ \text{CL}_{\text{ur}} = [1.25(10)] + 8.57 \]
\[ \text{CL}_{\text{ur}} = 21.1 \text{ mL/min per } 1.8 \text{ m}^2 \]
Ganciclovir is commonly used in solid-organ transplantation patients as prophylaxis against or treatment for cytomegalovirus infection.\textsuperscript{44} The inhibitory concentration (IC\textsubscript{50}) of ganciclovir against 50% of clinical isolates of cytomegalovirus ranges from approximately 0.1 - 2.8 mg/L (0.4 to 11 mmol/L).\textsuperscript{45} Consequently, trough concentrations should be maintained within this range, but caution is warranted as neutropenia has been associated with the attainment of ganciclovir trough concentrations exceeding 2.6 mcg/mL (2.6 mg/L; 10 mmol/L).\textsuperscript{45} If a patient with ESRD received the ganciclovir dose intended for a patient with normal renal function, the predicted trough concentrations would approach 5.2 mcg/mL (5.2 mg/L; 20 mmol/L). Consequently, a dosage modification would be necessary to avoid potential toxicity. The dosing regimen can be modified using the ratio of the predicted clearance values. The quotient or Q for this patient can be calculated as:

$$Q = \frac{C_{\text{CL,normal}}}{C_{\text{CL,un}}}$$

$$Q = 21.1/158.6$$

$$Q = 0.133$$

where $C_{\text{CL,un}}$ is the clearance in a patient with normal renal function and $C_{\text{CL,un}}$ is the clearance of the patient with impaired renal function.

The maintenance dose ($D_t$) for the patient or the adjusted dosing interval ($\tau_t$) may then be calculated from the following relationships, where $D_n$ is the normal dose and $\tau_n$ is the normal dosing interval:

$$D_t = D_n \times Q$$

$$\tau_t = \tau_n/Q$$

For this patient situation, the normal dose and dosing interval of ganciclovir would be 5 mg/kg and 12 hours, respectively. If we wish to maintain the dosing interval at 12 hours, then $D_t$ would be calculated as:

$$D_t = (5 \text{ mg/kg}) \times (0.133) = 0.67 \text{ mg/kg}$$

This regimen would result in decreased peak and trough concentrations compared to a patient with this degree of renal insufficiency who received a normal dosage regimen (Fig. 57–1, Scenario A). However, the peak concentrations would be lower and the trough concentrations higher than those observed when a patient with normal renal function received a standard regimen.

If one maintains $D_t$ and extends the dosing interval, $\tau_t$ would be calculated as:

$$\tau_t = \tau_n/Q = 12/0.133 = 90 \text{ hours}$$

This regimen would yield similar peak and trough concentrations in the renally impaired patient as in the patient with normal renal function, but there is a risk of missed doses with such an unorthodox interval (Fig. 57–1, Scenario B). In addition, the prolonged period below the steady-state drug concentration ($C_{\text{ss}}$) average concentration may be less than the optimal.

Finally, a practical dosing interval ($\tau_n$) may be selected and then a dose based on that interval can be calculated. If a dosage interval $\tau_n$ of 24 hours were selected, because in many institutions there is an increased risk of missed doses with longer dosing intervals, then the $D_t$ would be calculated as follows:

$$D_t = \frac{D_n \times Q \times \tau_n}{\tau_p}$$

$$= (5 \text{ mg/kg}) \times (0.133) \times 24/12$$

$$= 1.33 \text{ mg/kg}$$

This method would be most appropriate, as prolonged subtherapeutic concentrations are avoided and troughs are reduced (Fig. 57–1, Scenario C). The selection of which dosage-adjustment method to use to calculate an optimal regimen depends on the drug characteristics and the patient care situation. This dosage-adjustment method assumes that the protein binding and volume of distribution of the drug are not significantly altered by renal insufficiency. Thus, this approach cannot be used with accuracy for those drugs with demonstrated differences in these pharmacokinetic parameters.

If the volume of distribution ($V_{\text{p}}$) of a drug is significantly altered in CKD patients or in whom one desires to attain a specific maximum or minimum concentration, the estimation of a dosage regimen becomes more complex. If the relationship between $V_{\text{p}}$ and $C_{\text{ss}}$ has been characterized, then $V_{\text{p}}$ may be estimated. If one assumes that a one-compartment linear model can describe the drug, the predicted $V_{\text{p}}$ may then be used with the predicted elimination rate constant ($k$) of the drug to yield an adjusted-dosing interval and intravenous or oral dose. For orally administered drugs, the $\tau_t$ and the dose using equations originally proposed for IV dosing as:

$$\tau_t = [(\tau_t/k_t)](\ln[C_{\text{min}}/C_{\text{max}}]) + t_{\text{peak}}$$

$$D_{\text{po}} = \left[\frac{F \times C_{\text{ss}}}{k_t(k_t - k)}/[k_t(e^{-kt}/1 - e^{-kr})(e^{-kt}/1 - e^{-kr})]\right]$$

where $F$ equals bioavailability, $C_{\text{ss}}$ equals the desired plasma concentration at time $t$, and $k_t$ is the absorption rate constant. This approach allows for the individualization of an oral dosage regimen for attainment of specific peak and trough serum concentrations. If the drug is absorbed extremely rapidly, one can approximate the $\tau_t$ and the dose using equations originally proposed for IV dosing as:

$$\tau_t = [(\tau_t/k_t)](\ln[C_{\text{min}}/C_{\text{max}}]) + t_{\text{peak}}$$

$$D_{\text{po}} = \left[\frac{F \times C_{\text{ss}}}{k_t(k_t - k)}/[k_t(e^{-kt}/1 - e^{-kr})(e^{-kt}/1 - e^{-kr})]\right]$$

Digoxin is a frequently used oral medication for which the $V_{\text{p}}$ is decreased in CKD patients and for which one usually desires to closely control the plasma concentration time profile. The $V_{\text{p}}$ and $C_{\text{ss}}$ of digoxin can be estimated for a 70-kg (154 lb) patient with a $C_{\text{min}}$ of 12 mL/min per 1.73 m\textsuperscript{2} (0.11 mL/s/m\textsuperscript{2}) as summarized by Job\textsuperscript{47}:

$$V_{\text{p}} = 226 + [(298(C_{\text{ss}}))/(29.1 + C_{\text{ss}})]$$

$$= 226 + [(298(12))/(29.1 + 12)]$$

$$= 226 + 87.0$$

$$= 313 \text{ L}$$

$$\tau_{\text{fail}} = (0.88 \times C_{\text{ss}}) + 23 \text{ mL/min}$$

$$= 10.6 + 23$$

$$= 33.6 \text{ mL/min}$$

$$k_t = \frac{C_{\text{ss}}}{\tau_{\text{fail}}/V_{\text{p}}}$$

$$= (33.6 \text{ mL/min} \times 1440 \text{ min/d})/313 \text{ L}$$

$$= (48.3 \text{ L/d})/313 \text{ L}$$

$$= 0.154 \text{ day}^{-1}$$

The $\tau_{\text{fail}}$ is generally at 2 hours, and the $k_t$ from the literature is about 0.76 hour\textsuperscript{-1} or 18 day\textsuperscript{-1}. Thus, one now has all the information needed to calculate the $\tau_t$ and dose for this patient assuming the desired $C_{\text{min}}$ and $C_{\text{max}}$ are 0.8 and 1.4, respectively:

$$\tau_t = [(\tau_t/k_t)](\ln[C_{\text{min}}/C_{\text{max}}]) + t_{\text{peak}}$$

$$= [(\tau_t/0.76)](\ln[0.8/1.4]) + 2 \text{ hours}$$

$$= (6.49)(-0.56) + 2 \text{ hours}$$

$$= 3.6 \text{ days} + 2 \text{ hours}$$

$$\approx 4 \text{ days}$$

$$D_{\text{po}} = [(1.4)(313)(18 - 0.154)]/[18(e^{-0.154}(0.083))/1 - e^{-0.154}(0.083)/1 - e^{-0.154}(0.083)]$$

$$= 0.226 \text{ mg or}$$

$$\approx \text{ one 0.25 mg oral capsule every 4 days}$$
Alternatively, the predicted volume of distribution and elimination rate constant or the total-body clearance may be used to calculate a dose regimen that will maintain the desired average $C_{av}$ of the drug:

$$Dose \ (mg/h) = C_{av} \left( k_d \times V_{D} \right) \ or \ (CL_P)$$

Depending on how much variance above and below the average steady state one desires, the dosing interval may range from hourly to as infrequently as every 48 hours or longer. For example, if the calculated dose were 10 mg/h, the desired average steady-state concentration would be maintained with a dosing interval of 60 mg every 6 hours or 480 mg every 48 hours.

**PATIENTS RECEIVING CONTINUOUS RENAL REPLACEMENT THERAPY**

Continuous renal replacement therapies are used for the management of fluid overload and the removal of uremic toxins in patients with acute renal failure and other conditions. The several forms of continuous renal replacement therapy in clinical use today are extensively described in Chapter 51 and several dosage regimen individualization approaches are presented and critiqued. Which of these therapies will be optimal for a given patient is dependent on several factors, including bleeding risk, degree of hypercatabolism, acid–base balance, and experience of the healthcare provider team.

**PATIENTS RECEIVING CHRONIC PERITONEAL DIALYSIS**

Peritoneal dialysis, like other dialysis modalities, has the potential to affect drug disposition; however, drug therapy individualization is often less complicated in these patients as a result of the limited drug clearances achieved with the variants of this procedure (see Chapter 54). In general, hemodialysis is more effective in removing drugs than peritoneal dialysis such that if a drug is not removed by hemodialysis, it is unlikely to be significantly removed by peritoneal dialysis.

Many of the factors that are important in determining drug dialyzability for other treatment modalities pertain to peritoneal dialysis as well. Peritoneal dialysis involves the instillation of 1 to 3 L of dialysis solution into the peritoneal cavity. Waste products and other substances, including drugs, move from the blood and surrounding tissues into the dialysis solution by means of diffusion and ultrafiltration. Factors that influence drug dialyzability by peritoneal dialysis include drug-specific characteristics such as molecular weight, solubility, degree of ionization, protein binding, and volume of distribution. The intrinsic properties of the peritoneal membrane that affect drug removal include blood flow and peritoneal membrane surface area, which is approximately equal to the body surface area. There is an inverse relationship between peritoneal drug clearance and molecular weight, protein binding, and volume of distribution. Also, drug compounds that are ionized at physiologic pH will diffuse across the membrane more slowly than unionized compounds. Detailed reviews of the disposition of several drugs in chronic peritoneal dialysis patients are reported elsewhere. Anti-infective agents are the most commonly studied drugs because of their primary role in the treatment of peritonitis (see Chapter 54). Most other drugs can generally be dosed based on the residual renal function of the patient because the additional clearance by peritoneal dialysis is so small.

**PATIENTS RECEIVING CHRONIC HEMODIALYSIS**

Although many new hemodialyzers have been introduced in the past 20 years and more than 100 different ones were available in the United States in 2010, the effect of hemodialysis on drug disposition is rarely reevaluated after it is initially reported. Thus, most of the literature, especially for older medications, probably represents an underestimation of the impact of hemodialysis on its disposition.

The impact of hemodialysis on a patient’s drug therapy is dependent on several factors, including the characteristics of the drug, the dialysis conditions, and the clinical situation for which dialysis is performed. Drug-related factors that affect dialyzability include the molecular weight or size, degree of protein binding, and distribution volume. The vast majority of dialysis filters in use in the United States up until the mid-1990s were composed of cellulose, cellulose acetate, or regenerated cellulose (cuprophane) (see Chapter 54), and they were generally impermeable to drugs with a molecular weight greater than 1,000 Da. Drugs that are small but highly protein bound also are not well dialyzed because both of the principal binding proteins, $\alpha_1$-acid glycoprotein and albumin, have a very high molecular weight. Finally, those drugs that are widely distributed, $V_d > 2$ L/kg, are poorly removed by hemodialysis.

The hemodialysis procedure, be it acute for the management of AKI, intermittent 3 times a week or daily for an extended period or some combination thereof for the management of ESRD as well as the prescription for the patient can also dramatically affect the dialysis clearance of a medication. The primary factors that vary between patients are the composition of the dialysis filter, the filter surface area, the blood and dialysate flow rates, and whether or not the dialysis unit reuses the dialysis filter. Dialysis membranes in the 21st century are predominantly composed of semisynthetic or synthetic materials (e.g., polysulfone, polymethylmethacrylate, or polycrylonitrile). High-flux dialysis membranes have the largest pore sizes and more closely mimic the filtration characteristics of the human kidney. This allows the passage of most solutes, including drugs, that have a molecular weight of 20,000 Da or less. Thus, high-molecular-weight drugs such as vancomycin are extensively cleared by this mode of dialysis. An increase in removal has also been reported with several other drugs that have lower molecular weights (Table 57–7). The impact of hemodialysis on drug therapy should thus not be viewed as a generic procedure such that a certain percentage of a drug is removed with each dialysis session; neither should a “yes” answer regarding the dialyzability of drugs be considered sufficient information to make therapeutic decisions, since this provides no quantification of the impact of hemodialysis. Characteristics of the dialysis procedure that was utilized in the drug study, such as membrane composition and surface area and blood and dialysis flow rates, are thus critical data that should be

| TABLE 57-7 | Drug Disposition during Dialysis Depends on Dialyzer Characteristics |
|----------------|-------------------------|-------------------------|-------------------------|-------------------------|
| Drug            | Hemodialysis Clearance (mL/min)* | Half-Life during Dialysis (h) |
|                 | Conventional | High Flux | Conventional | High Flux |

Polymethylmethacrylate.
known before one uses the hemodialysis clearance data to prospectively design a drug dosing regimen for a hemodialysis patient.

The quantitative impact of hemodialysis on drug disposition can be calculated in several ways. The most commonly utilized means for assessing the effect of hemodialysis is to calculate the dialyzer clearance (CL\textsubscript{D}) of the drug. The CL\textsubscript{D} can be calculated by several approaches. The CL\textsubscript{D} from blood can be calculated as \( \text{CL}_{\text{D}} = \frac{Q_b}{V_p} \), where \( Q_b \) is blood flow through the dialyzer, \( A_p \) is the concentration of drug in blood going into the dialyzer, and \( V_p \) is the blood concentration of drug leaving the dialyzer. This equation is valid only if the drug concentrations are measured in whole blood and if the drug rapidly and completely distributes into red blood cells. Because drug concentrations are generally determined in plasma, the previous equation is usually modified to \( \text{CL}_{\text{D}} = \frac{Q_p}{V_p} \), where \( p \) represents plasma and \( Q_p \) is plasma flow, which equals \( Q_b (1 - \text{hematocrit}) \). This clearance calculation most accurately reflects dialysis drug clearance as most drugs do not significantly penetrate red blood cells or bind to formed blood elements. However, one must keep in mind that venous plasma concentrations may be artificially high and CL\textsubscript{p} will be low if plasma water is removed from the blood at a faster rate than drug. This tends to occur when extensive ultrafiltration is performed simultaneously with diffusion during dialysis.

The recovery clearance approach remains the benchmark for the determination of dialyzer clearance and it can be calculated as:

\[
\text{CL}_{\text{D}} = R / \text{AUC}_{0-t}
\]

where \( R \) is the total amount of drug recovered unchanged in the dialysate and AUC\textsubscript{0-t} is the area under the predialyzer plasma concentration–time curve during the period of time that the dialysate was collected. To determine the AUC\textsubscript{0-t}, at least two and preferably three to four plasma concentrations should be obtained during dialysis.

The hemodialysis clearance values reported in the literature may vary significantly depending on which of these methods were used to calculate CL\textsubscript{D}. The principal reason for this is that for most medications we do not know the degree and rapidity with which the drug crosses the red blood cell membrane. Because the CL\textsubscript{D} method incorporates no assumption of the degree of red blood cell permeability, it can be reliably used as the benchmark value. The primary limitation of this calculation is that the concentrations of the drug in the dialysate may be below the sensitivity limits of the assay.

The following principles may be used to generate a drug dosage regimen recommendation for hemodialysis patients by using a value of CL\textsubscript{D} that is reported in the literature. Because clearance terms are additive, the total clearance during dialysis can be calculated as the sum of the patient’s residual renal and nonrenal clearance during the interdialytic period (CL\textsubscript{RES}) and dialyzer clearance (CL\textsubscript{D}):

\[
\text{CL}_t = \text{CL}_{\text{RES}} + \text{CL}_{\text{D}}
\]

The half-life during the period between dialysis treatments and during dialysis can then be calculated from the following relationships using an estimate of the drug’s distribution volume (\( V_D \)), which can be obtained from the literature:

\[
\begin{align*}
\text{t}_1/2_{\text{HD}} = 0.693[\text{V}_D/\text{CL}_{\text{RES}}] & \quad \text{t}_1/2_{\text{HD}} = 0.693[\text{V}_D/(\text{CL}_{\text{RES}} + \text{CL}_{\text{D}})]
\end{align*}
\]

Once the key pharmacokinetic parameters have been estimated, they may be used to simulate the plasma concentration–time profile of the drug for the individual patient and then one can ascertain how much drug to administer and when. This approach to drug therapy individualization can be accomplished in a stepwise fashion assuming first-order elimination of the drug and a one-compartment model.

For example, a 34-year-old male with ESRD was admitted to a hospital from the outpatient hemodialysis unit, where he experienced shaking and chills and had a temperature of 40°C (104°F). He weighed 70 kg (154 lb) and was 69 inches (175 cm) tall, had a residual CL\textsubscript{D} of 3 mL/min (0.05 mL/s), and received high-flux dialysis for 3 hours 3 times a week on an F80 polysulfone dialyzer. He received 140 mg of gentamicin at the end of his most recent hemodialysis treatment, which ended less than an hour prior to admission to the hospital.

The first step is to estimate the patient’s pharmacokinetic parameters of gentamicin on the basis of published population data. The volume of distribution in this patient is 23.1 L (0.33 L/kg × 70 kg), and his residual total body clearance (CL\textsubscript{RES}) estimated from the relationship between CL and creatinine clearance [CL\textsubscript{RES} = CL\textsubscript{CR} × 0.98] is 3 mL/min (0.05 mL/s) or 0.176 L/h. The elimination rate constant can be approximated as:

\[
k = \text{CL}_{\text{RES}} + V_D
\]

\[
= 0.176 \text{ L/h} + 23.1 \text{ L}
\]

\[
= 0.0076 \text{ hr}^{-1}
\]

The hemodialysis clearance of gentamicin is dependent on the dialyzer and a value of 116 mL/min is a reasonable estimate for this dialyzer.

One now can predict what the plasma concentrations of gentamicin will be over the next 24 to 48 hours, assuming the infusion time for the drug (\( t \)) was 30 minutes. The concentration at the end of the 30-minute infusion (\( C_{\text{max}} \)) would be:

\[
C_{\text{max}} = \frac{\text{Dose}/t(1-e^{-kt})}{\text{CL}_{\text{RES}}}
\]

\[
C_{\text{max}} = \frac{(280 \text{ mg/h})[1 - e^{-(0.0076)0.5}]}{0.176 \text{ L/h}}
\]

\[
C_{\text{max}} = (1.944 \text{ mg/L})(0.003) = 6.0 \text{ mg/L}
\]

The plasma concentration prior to the next dialysis session (\( C_{\text{D1}} \)), which is 44 hours away, and the concentration four hours later after dialysis (\( C_{\text{D3}} \)) can be calculated as:

\[
C_{\text{D1}} = C_{\text{max}} \times e^{-t/(\text{CL}_{\text{RES}}/V_D)} 
\]

\[
= 6.0 \times e^{-0.0076 \times 44}
\]

\[
= 4.3 \text{ mg/L}
\]

\[
C_{\text{D3}} = C_{\text{D1}} \times e^{-t/(\text{CL}_{\text{RES}} + \text{CL}_{\text{D}})}
\]

\[
= 4.3 \times e^{-(0.176 + 0.0076)/23.1) \times 4}
\]

\[
= 4.3 \times e^{-0.309 \times 4}
\]

\[
= 1.25 \text{ mg/L}
\]

On the basis of these data, a second dose will likely be required at the end of the next dialysis session as one generally desires to have gentamicin concentrations fall below 2 mg/L (2 mcg/mL; 4.2 mmol/L) before administering another dose.

During this interdialytic interval, several blood samples were collected to characterize this patient’s residual gentamicin clearance, distribution volume, and the clearance of gentamicin during dialysis. Blood samples were therefore collected at the following times after the first dose:

**DAY 1:** 7 PM (2 hours after dose) 6.5 mg/L or mcg/mL (13.6 mmol/L)

**DAY 2:** 8 AM (39 hours after dose; just before dialysis) 4.1 mg/L or mcg/mL (8.6 mmol/L)

**DAY 3:** 12 noon (immediately after dialysis) 2.0 mg/L or mcg/mL (4.2 mmol/L)
The $C_{\text{res}}$ can be calculated by back-extrapolation to the end of the infusion as described in Chapter 8. The elimination rate during the interdialytic period ($k_{ID}$) and during dialysis ($k_{ID}$), and the $V_p$ can be calculated as:

$$k_{ID} = \frac{\ln C_p/C_0}{\Delta t}$$

$$V_p = \frac{Dose/t'}{k_{ID} + \left(1 - e^{-k_{ID}t'}\right)}$$

where $\Delta t$ is the time in hours between the two measured concentrations and $C_{\text{res}}$, the gentamicin concentration in plasma prior to the administration of the first dose is zero.

The patient’s residual clearance ($CL_{\text{res}}$) of gentamicin can then be calculated as:

$$CL_{\text{res}} = V_p \times k_{ID}$$

$$CL_{\text{res}} = 20.0 \times 0.0125 = 0.25 \text{ L/h or 4.2 mL/min}$$

The dialyzer clearance ($CL_D$) can be calculated as follows because one knows the total clearance during dialysis ($CL_T$) and $CL_{\text{res}}$:

$$CL_D = CL_T - CL_{\text{res}}$$

$$CL_D = (0.179/h \times 20.0L) - 4.2 \text{ mL/min}$$

$$CL_D = (3.6L/h or 59.6 \text{ mL/min}) - 4.2 \text{ mL/min}$$

$$CL_D = 55.4 \text{ mL/min}$$

The ultimate reason for measuring the plasma concentrations of aminoglycosides and several other agents is to individualize the patient’s dosage regimen to achieve a bacteriologic cure while preserving residual renal function. Thus there remains one important step in our evaluation: the calculation of the dose this patient should receive next. The two factors that enter into this decision are the desired peak and trough concentrations and the degree of rebound in drug concentrations, after the end of dialysis. Because gentamicin concentrations have been noted to increase by approximately 25% within 1.5 to 2 hours after the end of hemodialysis, the trough concentration of this patient can be considered to be 2.5 mg/L (2.0 mg/L x 1.25). Although this value is higher than one might like to maintain in an individual with normal renal function, a prolonged period of almost 24 hours would be required just to have the concentration drop below 2.0 mg/L (2.0 mcg/mL; 4.2 mmol/L). Assuming the desired peak concentration was 7.0 mg/L (7.0 mcg/mL; 14.6 mmol/L), the postdialysis dose this patient would need can then be calculated using the simplified approach below, because the elimination half-life is extremely prolonged relative to the infusion time, and thus minimal drug is eliminated during the infusion period:

$$Dose = V_p \times (C_{\text{max}} - C_{\text{min}})$$

$$= 20.0 \times (7.0 - 2.5) = 90 \text{ mg}$$

It is common practice in most hemodialysis units to administer drugs after the patient has received dialysis on the premise that it is desirable to minimize the loss of drug that would result from the additional clearance during hemodialysis. Certainly, administration of antihypertensive agents and vasoactive drugs should be avoided in the hours prior to a hemodialysis session to minimize the likelihood of hypotension. However, emerging pharmacokinetic and pharmacodynamic considerations suggest that this may not be the optimal approach for several other agents, such as aminoglycosides and vancomycin. Two evaluations of predialysis and one of intradialytic dosing of aminoglycosides indicate that similar peak concentrations, a prime indicator of efficacy, can be obtained in these scenarios relative to those observed with postdialysis dosing. The area under the concentration–time curve during the dosing interval and the subsequent predialysis concentrations were noted to be significantly reduced and thus the risk of ototoxicity and further renal injury may be minimized. The best dosing schedule, a dose roughly twice that traditionally employed for postdialysis administration, in the 26 patients evaluated by Teigen et al., resulted in the achievement of the desired peak and area under the concentration–time curve in approximately 90% of patients. Although the administration of traditional doses of tobramycin (1.5 mg/kg) or vancomycin (1,000 mg) during dialysis has been associated with markedly lower areas under the concentration–time curve than those observed when the same dose was administered postdialysis; consequently, higher dosage regimens are usually necessary to compensate for the additional loss of drug during the dialysis procedure. It is highly recommended that aminoglycoside and vancomycin concentrations in hemodialysis patients be measured after the first dose and dialysis session and so that the dosage regimen can be individualized accordingly using Bayesian methodology whenever possible.

### CONCLUSIONS

Subtherapeutic or supratherapeutic responses to drugs in patients with renal insufficiency are often misinterpreted and not recognized as such. The adverse outcomes associated with inappropriate drug dosing have not been quantified but do warrant future investigations. Sound pharmacokinetic principles, used in concert with reliable population pharmacokinetic estimates, should ultimately yield the optimal approach to drug dosage regimen design for patients with renal insufficiency. Individualization of therapy should be undertaken whenever clinical therapeutic monitoring tools are available. The key action step is to use the knowledge we have to improve patient outcomes. The recent study of van Dijk et al. is an unfortunate reminder of how far we still have to go. They observed that although dosage adjustments based on renal function were warranted in 24% of the prescriptions of the patients with $CL_L$ less than 51 mL/min (0.85 mL/s), such adjustments were only performed in 59% of cases.

### ABBREVIATIONS

$A_D$: concentration of drug in blood going into the dialyzer (arterial side)

$A_p$: concentration of drug in plasma going into the dialyzer (arterial side)

AUC$_{th}$: the area under the predialyzer plasma concentration–time curve during hemodialysis

$C_L$: concentration of the drug in the plasma going into a filter

$C_{al}$: plasma concentration after dialysis

$C_{av}$: average plasma concentration

$C_{al}^D$: plasma concentration prior to the next dialysis session

$C_{al}^D$: concentration of drug in the dialysis fluid

$C_{av}^D$: average steady-state plasma concentration

CL: total-body clearance
REFERENCES

KEY CONCEPTS

1. Hypovolemic hypotonic hyponatremia is relatively common in patients taking thiazide diuretics. Thiazide-induced hyponatremia is usually mild and relatively asymptomatic. Hyponatremia rarely if ever occurs with loop diuretics.

2. The syndrome of inappropriate secretion of antidiuretic hormone causes euclidean hypotonic hyponatremia. Common causes of this syndrome include lung cancer, central nervous system disorders, pulmonary disorders, and a variety of drugs.

3. Symptoms of hyponatremia are usually neurologic in nature and symptom severity depends both on the magnitude of the decrease in serum sodium concentration and the rate at which it developed. Treatment of hyponatremia is associated with a risk of osmotic demyelination syndrome, a severe neurologic complication that can develop if the rate of serum sodium correction exceeds 8 to 12 mEq/L (8–12 mmol/L) within 24 hours.

4. Asymptomatic or mildly symptomatic hyponatremic patients should generally be managed conservatively with treatment directed at the underlying cause. A 0.9% sodium chloride infusion can be cautiously used to correct the serum sodium in patients with hypovolemic hypotonic hyponatremia and moderate to severe symptoms. A 3% sodium chloride infusion can be cautiously used in patients with euclidean or hypovolemic hypotonic hyponatremia and moderate to severe symptoms.

5. Hyponatremia most commonly occurs when increased water or hypotonic fluid losses are not offset by increased water intake or administration. For example, patients with diabetes insipidus excrete large volumes of dilute urine, but usually develop hyponatremia only if their water intake does not increase to offset the increased water losses.

6. Symptoms of hyponatremia are usually neurologic in nature, and range in severity from weakness, lethargy, restlessness, irritability, and confusion to twitching, seizures, coma, and death. The severity of symptoms depends on both the magnitude of the increase in serum sodium and the rate at which it developed.

7. The treatment goals in patients with hypernatremia include cautious correction of the serum sodium concentration and, when appropriate, restoration of a normal extracellular fluid volume. Too rapid correction of the serum sodium can result in cerebral edema, seizures, neurologic damage, and possibly death. To minimize the risk of these complications, the serum sodium concentration should be corrected at a maximum rate of 0.5 to 1 mEq/L (0.5–1 mmol/L) per hour, depending on the rate of hypernatremia development, and be limited to no more than 10 mEq/L (10 mmol/L) per day.

8. Patients with central diabetes insipidus should be treated with intranasal desmopressin acetate, with goals of decreasing urine volume to less than 2 L per day while maintaining the serum sodium concentration between 137 and 142 mEq/L (137 and 142 mmol/L). Patients with nephrogenic diabetes insipidus should be treated by correcting the underlying cause when possible, and sodium chloride restriction in conjunction with a thiazide diuretic to decrease the extracellular fluid volume by approximately 1 to 1.5 L.

9. Edema can develop as a primary defect in renal sodium handling or as a response to a decreased effective circulating volume. It is usually first detected in the feet or pretibial areas of ambulatory patients. Pulmonary edema, evidenced by auscultatory crackles, can be life-threatening.

10. Diuretics are the primary pharmacologic means for achieving the desired therapeutic outcomes of minimization of edema and improving organ function. Diuretic resistance can be overcome by using an increased dose or by using a combination of a loop diuretic and a thiazide or thiazide-like diuretic.

The human body tightly regulates blood volume and plasma osmolality as both are essential for normal cellular function. Blood volume is important because it is a determinant of effective tissue perfusion which is required to deliver oxygen and nutrients to and remove metabolic waste products from tissues. Plasma osmolality is an important determinant of intracellular volume. Maintenance of normal intracellular volume is particularly critical in the brain, where alterations can result in significant neural dysfunction and potentially death.

The homeostatic mechanisms for regulating blood volume and plasma osmolality involve control of sodium and water balance. Interestingly, the homeostatic mechanisms for controlling blood volume are focused on controlling sodium balance. In contrast, the homeostatic mechanisms for controlling plasma osmolality, which is largely determined by serum sodium concentration, are focused on controlling water balance. Thus, sodium and water balance are closely related and are frequently considered together. Disorders of sodium and water homeostasis are common and potentially serious.
It is important for clinicians to understand these disorders because they can both be caused by and treated with medications. This chapter reviews the etiology, classification, clinical presentation, and therapy for disorders of sodium and water homeostasis.

**SODIUM AND WATER HOMEOSTASIS**

Hypo- and hypernatremia are syndromes of altered plasma tonicity and cell volume that reflect a change in the ratio of total exchangeable body sodium to total body water. Many factors affect tonicity and water balance and a sound understanding of the pathogenesis and evaluation approaches are of utmost importance if one is to successfully prevent and manage these syndromes.

Sixty percent of total body water is located intracellularly, whereas 40% is contained in the extracellular space. Sodium and its accompanying anions, chloride and bicarbonate, comprise more than 90% of the total osmolality of the extracellular fluid (ECF), whereas intracellular osmolality is primarily dependent on the concentration of potassium and its accompanying anions (mostly organic and inorganic phosphates). The differential concentrations of sodium and potassium in the intra- and extracellular fluid are maintained by the sodium-potassium-adenosine triphosphatase (Na⁺-K⁺-ATPase) pump. Most cell membranes are freely permeable to water, and thus the osmolality of intra- and extracellular body fluids is the same.

Solutesthat cannot freely cross cell membranes, such as sodium, are referred to as effective osmoles. The concentration of effective osmoles in the ECF determines the tonicity of the ECF, which directly affects the distribution of water between the extra- and intracellular compartments. Addition of an isotonic solution to the ECF will result in no change in intracellular volume because there will be no change in the effective osmolality of the ECF. Addition of a hypertonic solution to the ECF, however, will result in a decrease in cell volume, whereas addition of a hypotonic solution to the ECF will result in an increase in cell volume. Table 58–1 summarizes the composition of commonly used intravenous solutions and their respective distribution into extracellular and intracellular compartments following infusion.

The serum sodium concentration is tightly regulated, and usually varies by no more than 2% to 3%. Regulation of serum sodium concentration occurs indirectly via mechanisms that control its determinants, plasma osmolality, and blood volume. The kidney regulates water excretion through a feedback mechanism with the hypothalamus, such that the serum osmolality remains relatively constant (275–290 mOsm/kg [275–290 mmol/kg]) despite day-to-day variations in water intake. Plasma osmolality is largely determined by the concentrations of sodium and the accompanying anions chloride and bicarbonate, and can be estimated as:

\[
\text{Sosm} = (2 \times S_{Na}) + \left( \frac{B_{glucose}}{18} \right) + (\text{BUN}/2.8)
\]

where Sosm = serum osmolality in millimoles per kilogram; \( S_{Na} \) = serum sodium concentration in mM/L; \( B_{glucose} \) = glucose concentration in mg/dL; and \( \text{BUN} \) = blood urea nitrogen concentration in mg/dL. Alternatively, when using SI units the equation becomes:

\[
\text{Sosm} = (2 \times S_{Na}) + (B_{glucose}) + (\text{BUN})
\]

where Sosm = serum osmolality in millimoles per kilogram; \( S_{Na} \) = serum sodium concentration in mmol/L; \( B_{glucose} \) = glucose concentration in mmol/L; and \( \text{BUN} \) = blood urea nitrogen concentration in mmol/L.

Arginine vasopressin (AVP), commonly known as antidiuretic hormone (ADH), is released from the posterior pituitary when the plasma osmolality increases by 1% to 2% or more. AVP binds to the vasopressin 2 (V2) receptors on the basolateral surface of renal tubular epithelial cells, resulting in the insertion of water channels (aquaporin 2) into the apical tubular lumen surface of the cell. Water can then pass through the cell into the peritubular capillary space where it is then reabsorbed into the systemic circulation. An increase in serum osmolality sensed in the hypothalamus results not only in AVP release, but also in stimulation of thirst. The combination of an increase in water intake and a decrease in water excretion results in a decrease in the serum osmolality and inhibition of AVP secretion once the plasma osmolality is restored to normal.

Nonosmotic release of AVP occurs when a decrease in a person’s effective circulating blood volume results in a decrease in systemic blood pressure. The effective circulating volume is that part of the ECF that is located in the arterial system and is responsible for organ perfusion. A decrease in the effective circulating volume (more accurately, the pressure associated with that volume) activates arterial baroreceptors in the carotid sinus and glomerular afferent arterioles, resulting in stimulation of the renin-angiotensin system and increased synthesis of angiotensin II. Angiotensin II stimulates both nonosmotic release of AVP and thirst. This volume stimulus overrides osmotic inhibition of AVP release, and conservation of water fosters restoration of effective circulating volume and blood pressure at the expense of hypo-osmolality.

Proper assessment of a patient with an abnormal serum sodium concentration requires knowledge of the fact that changes in the serum sodium concentration do not necessarily correlate with changes in ECF volume or sodium content as the sodium concentration is determined by the ratio of the ECF sodium content and ECF volume. Although hyponatremia and hypernatremia can be associated with conditions of high, low, or normal ECF sodium and volume, both conditions are most commonly the result of abnormalities of water metabolism.

**HYPONATREMIA**

**EPIDEMIOLOGY AND ETIOLOGY**

Hyponatremia (serum sodium <135 mEq/L [<135 mmol/L]) is the most common electrolyte abnormality encountered in clinical
Although its prevalence is not well established and varies with the patient population studied, it has been estimated to be as high as 28% in patients admitted to an acute care hospital. Mild hyponatremia (serum sodium <136 mEq/L [<136 mmol/L]) was observed in 42.6%, while 6.2% of patients had values <126 mEq/L (<126 mmol/L), and only 1.2% had values <116 mEq/L (<116 mmol/L). The incidence has been reported to be as high as 21% in patients seen in ambulatory hospital clinics, and 7% in community clinics. Drug-induced hyponatremia, especially that associated with diuretics and psychotropic medications, is more commonly seen in women than men. Increasing age (>30 years) is also clearly a risk factor for hyponatremia, independent of gender.

Hyponatremia incidence in the nursing home setting is 2-fold higher than that observed in similar aged-community dwelling individuals. Over 75% of these episodes were precipitated by increased fluid intake of hypotonic oral or intravenous fluids. Similarly, the ingestion of excessive quantities of fluids has been identified as a key risk factor in marathon runners who develop hyponatremia. Although women had a 3-fold higher rate of hyponatremia, smaller body size and longer racing time, not gender, appear to be the principal factors which account for the increased incidence.

Recognition of the high prevalence of hyponatremia is important because this condition is associated with significant morbidity and mortality. Transient or permanent brain dysfunction can result from either the acute effects of hypo-osmolality or from too rapid correction of hypo-osmolality in patients with symptomatic hyponatremia. Hyponatremia is predominantly the result of an excess of extracellular water relative to sodium because of impaired water excretion. The kidney normally has the capacity to excrete large volumes of dilute urine after ingestion of a water load. Nonosmotic release of AVP, however, can lead to retention of water and to a drop in serum sodium concentration, despite a fall in both serum and intracellular osmolality. The causes of nonosmotic release of AVP include hypovolemic, decreased effective circulating volume as seen in patients with chronic heart failure (CHF), nephrosis, and cirrhosis. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is also a common cause of hyponatremia which is associated with oncologic disease, especially small cell lung cancer. The pathophysiology, clinical features, and management of hyponatremia are detailed below.

**PATHOPHYSIOLOGY**

Hyponatremia can be associated with normal, increased, or decreased plasma osmolality, depending on its cause (Fig. 58-1). Hyponatremia in patients with normal serum osmolality can be caused by hyperlipidemia or hyperproteinemia. Historically, this form of hyponatremia, termed pseudohyponatremia, was an artifact of the method of serum sodium concentration measurement. This laboratory artifact is uncommon today and has been overcome with the use of ion-specific electrodes to measure the serum sodium concentration. If the sodium concentration in a laboratory is still measured by flame photometry, the volume of serum will be overestimated because the elevated lipids or proteins account for a greater proportion of the total volume of the sample (Fig. 58-2). Because the sodium is distributed in only the water component of serum, the measured serum sodium concentration is falsely decreased. The
measurement of serum osmolality, however, is not significantly affected, leading to a discrepancy between the calculated and measured serum osmolality.

Hyponatremia associated with increased serum osmolality, termed hypertonic hyponatremia, suggests the presence of excess, nonsodium-effective osmolytes in the ECF. This is most frequently encountered in patients with hyperglycemia. Elevated concentrations of glucose provide effective plasma osmoles, resulting in diffusion of water from the cells into the extracellular compartment, thereby expanding the ECF, which results in decrease in the serum sodium concentration. For every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration, the serum sodium level decreases by 1.7 mEq/L (1.7 mmol/L), and the serum osmolality increases by 2 mOsm/kg (2 mmol/kg). It should be noted that this correction is only a rough estimate because the increase in serum sodium varies substantially with the degree of hyperglycemia. Other substances such as mannitol, glycine, and sorbitol that do not cross cellular membranes provide effective osmoles and can also cause hypertonic hyponatremia. The presence of these unmeasured osmoles should be suspected in patients with hypertonic hyponatremia if there is a significant osmolal gap, that is the difference between the measured and calculated plasma osmolality.

Hyponatremia associated with decreased plasma osmolality, termed hypotonic hyponatremia, is the most common form of hyponatremia and has many potential causes (see Fig. 58–1). An important step in the diagnostic evaluation of patients with hypotonic hyponatremia is clinical assessment of the patient's extracellular fluid volume. Categorization of these patients into one of three groups (decreased, increased, or clinically normal ECF volume) is very helpful in identifying the pathophysiologic mechanisms responsible for the hyponatremia and an appropriate treatment regimen.

**Hypovolemic Hypotonic Hyponatremia**

Most patients with ECF volume contraction lose fluids that are hypotonic relative to plasma and thus can be transiently hypernatremic. This includes patients with fluid losses caused by diarrhea, excessive sweating, and diuretics. This transient hypernatremic hyperosmolality results in osmotic release of AVP and stimulation of thirst. If sodium and water losses continue, more AVP is released as a result of hypovolemia. Patients who then drink water or who are given hypotonic fluids intravenously retain water and develop hyponatremia. These patients typically have a urine osmolality greater than 450 mOsm/kg (greater than 450 mmol/kg), reflecting the presence of AVP and formation of a concentrated urine. The urine sodium concentration is <20 mEq/L (<20 mmol/L) when sodium losses are extrarenal, as in patients with diarrhea, and >20 mEq/L (>20 mmol/L) in patients with renal sodium losses, as occurs in the setting of diuretic use or adrenal insufficiency.

1 Hypotonic hyponatremia is relatively common in patients taking thiazide diuretics. Thiazide-induced hyponatremia is usually mild, but can occasionally be severe and symptomatic. It typically develops within 2 weeks of the initiation of therapy, but can occur late in therapy, particularly if there has been a recent increase in the diuretic dose or other causes of hyponatremia develop.

The mechanism of thiazide-induced hyponatremia is likely related to the balance of its direct and indirect effects. Thiazides exert their diuretic effect by blocking sodium reabsorption in the distal tubules of the renal cortex, thereby increasing sodium and water removal from the body. The resulting decrease in effective circulating volume stimulates AVP release. Increased AVP release results in increased reabsorption of free water in the collecting duct, as well as increased water intake because of stimulation of thirst. Hyponatremia develops when the net result of these effects is the loss of more sodium than water.

Interestingly, hyponatremia occurs infrequently with loop diuretics. This difference between thiazide and loop diuretics likely relates to their different sites of action. Loop diuretics exert their diuretic effect by blocking sodium reabsorption in the ascending limbs of the loop of Henle, many of which are located in the renal medulla. This action decreases medullary osmolality. Thus, when the loop diuretics decrease effective circulating volume and stimulate AVP release, less water reabsorption occurs in the collecting ducts than would occur if the osmolality of the renal medulla were normal. Thiazide diuretics do not alter medullary osmolality as their site of action is located in the renal cortex rather than in the medulla. In addition, most loop diuretics have a shorter half-life than the thiazides, and patients can therefore replete the urinary sodium and water losses prior to taking the next dose, thereby minimizing AVP stimulation.

**Euvolemic Hypotonic Hyponatremia**

Euvolemic hypotonic hyponatremia is associated with a normal or slightly decreased ECF sodium content and increased total body water and ECF volume. The increase in ECF volume is usually not sufficient to cause peripheral or pulmonary edema, and thus patients appear clinically euvolemic. Euvolemic hyponatremia is most commonly the result of SIADH release. In this syndrome, water intake exceeds the capacity of the kidneys to excrete water, either because of an increased release of AVP via nonsomotic and/or nonphysiologic processes or enhanced renal sensitivity to AVP.

The urine osmolality in patients with SIADH is generally greater than 100 mOsm/kg (greater than 100 mmol/kg), and the urine sodium concentration is usually greater than 20 mEq/L (greater than 20 mmol/L) as a result of the ECF volume expansion.

The most common causes of SIADH include tumors such as small cell lung cancer, central nervous system disorders (e.g., head trauma, stroke, meningitis, and pituitary surgery), as well as pulmonary disease. Patients with renal insufficiency, adrenal insufficiency, and hypothyroidism can also present with euvolemic hyponatremia, and the evaluation of patients with suspected SIADH should always include consideration of these disorders. A wide variety of drugs can also cause SIADH by enhancing AVP release, the renal effect of AVP or by unknown mechanisms.

(Table 58–1) The differential diagnosis of euvolemic hypotonic hyponatremia also includes primary or psychogenic polydipsia. Patients with this disorder drink more water (usually >20 L/day) than the kidneys can excrete as solute-free water. Unlike SIADH, however, AVP is suppressed, resulting in a urine osmolality that is less than 100 mOsm/kg (less than 100 mmol/kg). The urine sodium is typically low (<15 mEq/L [<15 mmol/L]) as a result of urinary dilution.

Hyponatremia can develop with more modest water intake in patients who are ingesting a very low-solute diet, such as a low-sodium vegetarian diet.

**Hypervolemic Hypotonic Hyponatremia**

Hyponatremia associated with an increase in ECF volume occurs in conditions in which renal sodium and water excretion are impaired. Patients with cirrhosis, congestive heart failure, and nephrotic syndrome have an expanded ECF volume and edema, but a decreased effective circulating volume. This decreased volume results in renal sodium retention, and eventually ECF volume expansion and edema. At the same time, there is nonsomotic release of AVP and retention of water in excess of sodium, which perpetuates the hyponatremia.

**CLINICAL PRESENTATION**

Patients with chronic, mild hyponatremia (serum sodium concentration greater than 125–130 mEq/L) [greater than
125–130 mmol/L) are usually asymptomatic, with hyponatremia being discovered incidentally when serum electrolytes are measured for other purposes. However, recent data from a small number of carefully evaluated patients suggest that it might be more accurate to say that symptoms of mild hyponatremia are frequently unnoticed by both physician and patient. These data suggest that chronic, mild hyponatremia is associated with impairment of attention, posture, and gait, all of which contribute to a substantially increased risk of falls. Even those who seem to be “asymptomatic” when formally tested can be shown to have impaired attention and gait to a degree that is compatible with a blood alcohol level of 0.06% (13 mmol/L).

Patients with moderate (serum sodium concentration of 115–125 mEq/L [115–125 mmol/L]) to severe (serum sodium concentration less than 110–115 mEq/L [110–115 mmol/L]) or rapidly developing hypotonic hyponatremia often present with a range of neurologic symptoms resulting from hypoosmolality-induced volume expansion of brain cells. Classic symptoms include nausea and malaise, headache, lethargy, restlessness, and disorientation, and in some cases, coma, permanent brain damage, respiratory arrest, brainstem herniation, and death.

The presence of these symptoms and their severity depend on both the magnitude of the hyponatremia and the rate at which the hyponatremia developed. The magnitude of the hyponatremia is important because serum osmolality decreases in direct proportion to the serum sodium concentration, and water movement into brain cells increases as serum osmolality decreases. The rate of osmolality change is an important factor because brain cells are able to adjust their intracellular osmolality to minimize cellular volume changes in response to volume changes, but time is required for this adaptation to occur. When a decline in plasma osmolality causes movement of water into brain cells, sodium, potassium, and organic osmolytes move out of the cells to decrease intracellular osmolality and minimize intracellular water movement. Organic osmolytes, such as myoinositol, are osmotically active substances that contribute substantially to controlling intracellular osmolality without directly altering cellular function. The various components of this adaptive mechanism occur over different time frames, with sodium and potassium efflux occurring over minutes to several hours and organic osmolyte efflux occurring over hours to days. Maximal compensation for a decrease in plasma osmolality typically requires up to 48 hours. Thus, acute changes in plasma osmolality are not compensated for instantaneously and are more likely to be associated with symptoms. Patients with concurrent respiratory failure and hypoxemia are at greater risk for adverse neurologic outcomes because hypoxemia diminishes the capacity of the brain to actively transport solute out of cells, leading to a higher incidence of cerebral edema.

Children and women have been noted to have poor clinical outcomes relative to adults and males. For example, women have a 25-fold higher risk of death or permanent neurological damage than men.

In addition to neurologic symptoms, patients with hypovolemic hyponatremia can present with signs and symptoms of hypovolemia, including dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, and orthostatic hypotension. These findings are helpful in identifying the type of hyponatremia.

The brain’s adaptation to changes in plasma osmolality is also associated with symptoms that can develop if hyponatremia is corrected too rapidly (i.e., >12 mEq/L [>12 mmol/L] per day). These patients might experience an acute decrease in brain cell volume, which contributes to the pathogenesis of osmotic demyelination syndrome. Patients with this complication might develop paraplegia, pseudo-bulbar palsy, and locked-in syndrome 5 to 7 days after treatment because of demyelination lesions in the pons. Patients who have a significant degree of cerebral adaptation to hypotonic hyponatremia are at higher risk of experiencing this syndrome. This is presumably because these patients have lower intracellular osmolalities at the initiation of therapy, which results in greater decreases in intracellular volume when the plasma osmolality is raised rapidly. Brain adaptation to increases in plasma osmolality requires time,

**CLINICAL PRESENTATION OF HYPONATREMIA**

**General**
- Hyponatremia is asymptomatic in most patients. Symptoms directly attributable to hyponatremia include neurologic dysfunction associated with cerebral edema.

**Symptoms**
- The presence and severity of symptoms are related both to the magnitude and rapidity of onset of the hyponatremia. Nausea and malaise are the earliest findings, followed by headache, lethargy, restlessness, and disorientation, and eventually seizures, coma, permanent brain damage, respiratory arrest, brainstem herniation, and death if hyponatremia is severe or develops rapidly. Other symptoms that can be seen with hyponatremia are those attributable to its underlying cause, such as volume depletion in patients with hypovolemic hypotonic hypo-osmolality or volume excess in patients with hypertensive hypotonic hyponatremia.

**Signs**
- General: Dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, and postural hypotension can be present in hypovolemic patients.
- Pulmonary: Noncardiogenic pulmonary edema has been described.
- Neurologic: Depressed reflexes. Rapid correction of hyponatremia can result in an acute decrease in brain cell volume resulting in demyelinating brain injury.

**Laboratory Tests**
- Serum sodium values <135 mEq/L (<135 mmol/L) are present. Plasma osmolality and urine sodium concentration can be helpful in diagnosing the cause. Tests including but not limited to serum glucose and lipids and tests to assess kidney and thyroid function should be conducted to identify or rule out potential causes.

**TREATMENT**

**Hyponatremia**

**DESIRED OUTCOME**
- The goal of treating patients with hypovolemic hypotonic hyponatremia is to resolve the underlying cause of the sodium and ECF volume deficits, and safely correct the hyponatremia. The treatment goals for hypervolemic and euvoletic hypotonic patients depend on the underlying cause of the hyponatremia and the severity of the patient’s symptoms. Patients with an acute onset of hyponatremia or severe symptoms require more aggressive therapy to correct the hypotonicity. The initial goal for these patients is to increase plasma tonicity enough to control the severe symptoms; this typically requires a relatively small increase in serum sodium concentration.
of approximately 5%. Once control of the severe symptoms is achieved, full correction of the serum sodium concentration should be achieved at a controlled rate. Asymptomatic patients and patients with mild to moderate symptoms do not require rapid correction of the serum sodium and the treatment is dictated by the underlying etiology. In all cases the goal is to avoid an increase in the serum sodium concentration more than 12 mEq/L (more than 12 mmol/L) in 24 hours. Some recommend that the maximal rate of correction not exceed 8 mEq/L (8 mmol/L) in 24 hours.

### GENERAL APPROACH TO TREATMENT

The following principles serve as general guidelines for the treatment of patients with hyponatremia: (1) It is important for both the short- and long-term management of the patient to treat the underlying cause of hyponatremia. (2) Appropriate treatment of patients with hypotonic hyponatremia requires balancing the risks of the hyponatremia versus the risk of osmotic demyelination syndrome. In general, patients who acutely developed moderate to severe hyponatremia and/or patients who have severe symptoms are at greatest risk and potentially benefit most from more rapid correction of their hyponatremia. (3) Active correction of hypovolemic hyponatremia is usually best accomplished with 0.9% sodium chloride solution as these patients have both sodium and water deficits. (4) Active correction of euvoiemic and hypervolemic hyponatremia in patients who do not require rapid correction is usually best accomplished by water restriction. Demeclocycline, vasopressin V2-receptor antagonists (vaptans), or sodium chloride plus a loop diuretic, can be used if the initial response to water restriction is not adequate. In patients with severe symptoms, 3% sodium chloride solution (possibly combined with furosemide) should initially be used to more rapidly correct the hyponatremia. Furosemide can be administered concurrently to enhance the serum sodium correction by increasing the excretion of water. (5) Long-term management is required for patients in whom the underlying cause of hyponatremia cannot be corrected. This can include water restriction, increasing sodium intake, and/or the use of an AVP antagonist. Application of these principles to the treatment of patients with various forms of hyponatremia is discussed in the following sections.

### ACUTE OR SEVERELY SYMPTOMATIC HYPOTONIC HYponATREMIA

A patient who has or is at high risk of experiencing severe symptoms caused by hyponatremia should receive either 3% or 0.9% sodium chloride solution until severe symptoms resolve. Resolution of severe symptoms frequently requires only a small, 3% increase in serum sodium, although some suggest that the initial target should be to increase serum sodium to approximately 120 mEq/L (120 mmol/L). The relative concentrations of urine sodium and potassium (osmotically effective urine cations) must be compared with those of the infusate in planning a treatment regimen for patients with hypotonic hyponatremia. For the serum sodium to increase after infusion of a solution of sodium chloride, the concentration of sodium in the infusate must exceed the sum of the sodium and potassium concentration in the urine to effect net-free water excretion.

Patients with SIADH often have urinary concentrations of osmotically effective urine cations that exceed the sodium concentration of 0.9% sodium chloride (154 mEq/L [154 mmol/L]) and thus these patients should be preferentially treated with 3% sodium chloride (513 mEq/L [513 mmol/L]). In this case use of isotonic sodium chloride carries the potential hazard of actually worsening hyponatremia. The relatively high concentration of urinary sodium in patients with SIADH stems from the fact that the ECF is expanded, thus minimizing reabsorption of sodium along the nephron. When the urine osmolality exceeds 300 mOsm/kg (300 mmol/kg), it is generally advisable to add an intravenous loop diuretic, not only to increase the excretion of solute-free water, but also to prevent volume overload, which can result from infusion of hypertonic sodium chloride. Intravenous furosemide, initially at a dose of 40 mg every 6 hours, is generally sufficient to prevent volume overload and to decrease the concentration of osmotically active urine cations to less than 150 mEq/L (less than 150 mmol/L).

Patients with hypovolemic hypotonic hyponatremia, conversely, can be treated with 0.9% sodium chloride solution. In contrast to patients with SIADH, patients with this condition avidly reabsorb sodium throughout the nephron when the effective circulating blood volume is decreased. Thus the urine osmolality is primarily comprised of urea, and the concentration of urine sodium is often less than 20 mEq/L (less than 20 mmol/L), which is substantially less than the sodium concentration in 0.9% sodium chloride solution. Use of 3% sodium chloride solution will also effectively correct hyponatremia in these patients, but its use should be reserved for situations requiring very rapid correction.

Hypervolemic hypotonic hyponatremic patients are particularly problematic to manage acutely because the sodium and volume required to minimize the risk of cerebral edema or seizures can worsen their already compensated hepatic, cardiac, or renal function. It is generally agreed that these patients should be treated with hypertonic sodium chloride and prompt initiation of fluid restriction. Loop diuretic therapy will also likely be required to facilitate urinary excretion of free water.

### DETERMINATION OF SODIUM CHLORIDE INFUSION REGIMEN

Several methods for determining the correct sodium chloride solution infusion regimen for a hyponatremic patient have been proposed. It is important to recognize that usual approaches provide only a rough estimate of the correct infusion regimen as their use involves known but yet incorrect assumptions. More accurate equations have recently been derived, but the benefits of this more complex approach relative to the approach outlined below remain to be determined.

One commonly used approach for estimation of the change in plasma sodium resulting from the infusion of 1 L of 3% or 0.9% sodium chloride solution is:

\[
\text{Change in } S_\text{Na} = (\text{IV}_{\text{Na}} - S_1^\text{Na}) \div (\text{BW} + \text{IV}_{\text{vol}})
\]

where \(S_1^\text{Na} = \text{initial patient serum sodium concentration} \), \(\text{IV}_{\text{Na}} = \text{sodium concentration of infusate} (154 \text{ mEq/L} [154 \text{ mmol/L}]) \) for 0.9% sodium chloride or 513 mEq/L (513 mmol/L) for 3% sodium chloride; \(\text{IV}_{\text{vol}} = 1 \text{ L of infusate} \); and BW = total body water (in liters), which can be estimated as a fraction of body weight (kilograms) as follows:

- 0.6 × body weight for children and men <70 years old
- 0.5 × body weight for men ≥70 years old and females <70 years old
- 0.45 × body weight for women ≥70 years old

The appropriate infusion volume for a given patient can then be estimated based on the proportion of the estimated change that would result from a 1-L infusion that is actually desired in that patient. Finally, an appropriate infusion rate can be calculated for this infusion volume to control the rate of increase in the serum sodium concentration.
For example, consider the case of a 170 centimeter (5 feet 7 inch), 60 kilogram (132 pound), 66-year-old woman who presents with nausea, vertigo, and disorientation that have developed over the past several days. She was started on carbamazepine 10 days ago for the treatment of trigeminal neuralgia. Her serum sodium is currently 108 mEq/L (108 mmol/L). Assuming this woman has carbamazepine-induced SIADH, an initial approach to treatment might include discontinuing her carbamazepine and partially correcting her hyponatremia by raising her sodium serum to approximately 120 mEq/L (120 mmol/L) over the first 24 hours of hospitalization. This should be an adequate response to alleviate her current symptoms, decrease the risk of more severe symptoms, and minimize the risk of osmotic demyelination syndrome. Assuming that use of 3% sodium chloride solution is appropriate, the infusion regimen required to increase her serum sodium to 120 mEq/L (120 mmol/L) over the next 24 hours can be calculated as follows:

\[
\text{Change in } S_{Na} \text{ with 1 L of infusate} = \left( \frac{120 \text{ mEq/L} - 108 \text{ mEq/L}}{(0.5 \text{ L/kg} \times 60 \text{ kg}) + 1.0 \text{ L}} \right) \times 1.0 \text{ mEq/L} \]

In SI units:

\[
(513 \text{ mmol/L} - 108 \text{ mmol/L}) ÷ [0.5 \text{ L/kg} \times 60 \text{ kg} + 1.0 \text{ L}] = 13.1 \text{ mmol/L} \text{ or } 13.1 \text{ mEq/L} \text{ per } 100 \text{ mL}
\]

Because infusion of 1 L of 3% sodium chloride solution would produce a 13.1 mEq/L (13.1 mmol/L) rise in the serum sodium, and we desire only a 12 mEq/L (12 mmol/L) increase, the appropriate infusion volume is 916 mL \[(12 \text{ mEq/L} ÷ 13.1 \text{ mEq/L} × 1,000 \text{ mL})\] or in SI units \[(12 \text{ mmol/L} ÷ 13.1 \text{ mmol/L} × 1,000 \text{ mL})\]. The approach to this calculation would be similar if 0.9% sodium chloride solution were used, except that the expected increase in serum sodium concentration would be only 1.5 mEq/L (1.5 mmol/L) per liter infused, and an infusion volume of approximately 8 L would be required to achieve the targeted serum sodium concentration.

In the presence of symptoms, the serum sodium should be increased by approximately 1.5 mEq/L (1.5 mmol/L) per hour over the first 2 to 4 hours (for a total of 3 to 6 mEq/L \[3 \text{ to 6 mmol/L}\]) or until the symptoms have resolved. Thus, an initial infusion rate of 114 mL/h \[1.5 \text{ mEq/L per hour} ÷ 1.31 \text{ mEq/L per 100 mL} \] or \[1.5 \text{ mEq/L per hour} ÷ 1.31 \text{ mmol/L per 100 mL} \] for SI units for the first 2 to 4 hours, followed by an infusion rate of approximately 23 to 31 mL/h for the next 20 to 22 hours, respectively, would be a reasonable initial treatment plan.

\[\text{ECFVD} = \text{ECFV}_{norm} - \text{ECFV}_{current} \]

\[\text{ECFVD} = \frac{\text{TBW}_{norm} \times 0.5 \text{ L/kg} \times 0.33} {\text{TBW}_{current} \times 0.5 \text{ L/kg} \times 0.33} - \frac{62 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33} {55.3 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33} = 1.1 \text{ L} \]

If the patient’s previous weight were not known, it could be roughly estimated based on sex, change in body weight, and age. For example, consider the case of a 56-year-old woman who was started on hydrochlorothiazide 10 days ago for the treatment of hypertension. She is 173 cm (5 ft 8 in) tall and weighed 62 kg (137 lb) at that time. Today she presents with complaints of mild nausea and “feeling dizzy” when she stands up. Her weight is now 55.5 kg (122 lb). Physical examination reveals dry mucous membranes and orthostatic hypotension. Her serum sodium is 125 mEq/L (125 mmol/L). The patient’s ECFVd could be estimated as follows:

\[\text{ECFVD} = \text{ECFV}_{norm} - \text{ECFV}_{current} \]

\[\text{ECFVD} = \frac{\text{TBW}_{norm} \times 0.5 \text{ L/kg} \times 0.33} {\text{TBW}_{current} \times 0.5 \text{ L/kg} \times 0.33} - \frac{62 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33} {55.3 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33} = 1.1 \text{ L} \]

The expected increase in the serum sodium concentration following infusion of 1 L of 0.9% sodium chloride (154 mEq/L \[154 \text{ mmol/L}\]) can be estimated as:

\[\text{Change in } S_{Na} \text{ with 1 L of infusate} = \left[ 154 \text{ mEq/L} - 125 \text{ mEq/L} \right] \times [0.5 \text{ L/kg} \times 55.3 \text{ kg} + 1.0 \text{ L}] = 1.0 \text{ mEq/L} \]

In SI units:

\[= \left[ 154 \text{ mmol/L} - 125 \text{ mmol/L} \right] \times \left[ 0.5 \text{ L/kg} \times 55.3 \text{ kg} \times 1.0 \text{ L} \right] = 1.0 \text{ mmol/L} \]
The patient’s sodium serum concentration can thus be predicted to be 126 mEq/L (125 mEq/L + 1.0 mEq/L) or 126 mmol/L (125 mmol/L + 1.0 mmol/L) following the infusion.

Because the overriding initial treatment goal is to restore effective circulating volume, it might be necessary to infuse 0.9% sodium chloride at 200 to 400 mL/h until symptoms of hypovolemia moderate. The infusion rate can then be decreased to 100 to 150 mL/h so that the serum sodium level increases by no more than 12 mEq/L (12 mmol/L) over the initial 24 hours. Infusion of 0.9% sodium chloride at rates greater than 250 mL/h should be used cautiously in patients with a history of left ventricular dysfunction or renal insufficiency. It is important to recognize that the rate of increase in the serum sodium concentration can substantially increase once hypovolemia has been corrected if infusion rates are not decreased. Once the ECFV is restored, AVP secretion will cease, and a rapid water diuresis can ensue, which can potentially result in an increase in the serum sodium at a rate greater than 12 mEq/L (greater than 12 mmol/L) per day. Ideally, the potential for this increase in correction rate is recognized prospectively and infusion rates are appropriately adjusted. Estimation of the patient’s ECFV at the initiation of therapy can help in this regard. If the serum sodium is observed to be increasing at a rate greater than 12 mEq/L (greater than 12 mmol/L) per day, the infusion should be changed to 0.45% sodium chloride, and the infusion rate set to one that approximates urine output (approximately 1.5–2 mL/kg per hour is a reasonable initial rate), to slow the rate of increase in the serum sodium concentration.

■ EVALUATION OF THERAPEUTIC OUTCOMES

Patients presenting with evidence of volume depletion should be reexamined frequently during the initial few hours of therapy. The serum sodium concentration should be measured every 2 to 4 hours to allow timely adjustment of the rate and composition of intravenous fluids to avoid an increase in the serum sodium greater than 12 mEq/L (greater than 12 mmol/L) per day. Intravenous 0.9% sodium chloride should be administered judiciously in patients with a history of congestive heart failure or renal insufficiency, with frequent assessments of the cardiopulmonary examination so the infusion rate can be appropriately decreased at the earliest sign of pulmonary congestion.

NONEMERGENT EUVOLEMIC HYPOTONIC HYponATREMIA

The fact that an individual’s neurological performance is restored to normal with correction of their hyponatremia provides a rationale for therapeutic management of all patients to maintain their serum sodium above 135 mEq/L (135 mmol/L). Long-term management is thus required for patients in whom the underlying cause of hyponatremia is not readily correctable. The treatment of SIADH always involves water restriction and correction of the underlying cause, if possible. Drugs that could be contributing should be identified and discontinued. The goal is to induce negative water balance by restricting water intake to less than 1,000 to 1,200 mL/day, such that water losses from insensible sources (skin and lung) and from obligatory urine and fecal losses exceed intake. Daily insensible water losses via skin and lungs are approximately 900 mL/day, whereas approximately 200 mL and a minimum of 500 mL/day is lost in stool and in urine output, respectively. Because approximately 850 mL of water per day is ingested in food, and an additional 350 mL are generated from oxidative processes, the water intake reduction should result in a negative water balance of several hundred milliliters per day. Other goals include maintenance of the serum sodium level above 125 mEq/L (125 mmol/L) to prevent symptoms of hypotonicity, and avoidance of iatrogenic hypo- or hypervolemia.

Patients with chronic SIADH who are unable to restrict water sufficiently to maintain the serum sodium greater than 120 to 125 mEq/L (greater than 120–125 mmol/L) can be treated by increasing solute intake with sodium chloride and/or loop diuretics. Sodium chloride or urea tablets increase the obligatory daily solute excretion, which augments the capacity for renal water excretion. The goal is to increase the daily solute intake and excretion to approximately 900 mOsm (900 mmol) per day. Because an average diet contains approximately 600 mOsm (600 mmol), 9 grams of sodium chloride would be required to increase the osmolar excretion to 900 mOsm/day (900 mmol/day) (each 1-g sodium chloride tablet contains 17 mmol of sodium and 17 mmol of chloride). Because extracellular volume expansion is an expected adverse effect, a loop diuretic should be administered concurrently to avoid pulmonary congestion and peripheral edema. Loop diuretics also enhance water excretion by limiting the formation of the medullary concentration gradient.

Demeclocycline is another treatment option for patients who are not adequately controlled by fluid restriction alone. Demeclocycline inhibits tubular AVP activity, resulting in increased water excretion.4,5 The usual dose of demeclocycline is 300 mg 2 to 4 times daily. Because of its delayed onset of action (3–6 days), this agent has no role in the acute management of severe hyponatremia, and dosage changes should be made no more frequently than every 3 to 4 days during its use.5,6 Demeclocycline should not be used in patients with liver disease or compromised fluid intake, who are at high risk for demeclocycline-induced renal tubular toxicity and acute renal failure, or in children because it can interfere with bone development.1,4,11

The historic therapeutic options of water restriction, diuretic therapy, and increased sodium intake have recently been augmented with the introduction of AVP antagonists or "vaptans" (Table 58–2). These agents can be used to treat SIADH, as well as other causes of euclidean and hypervolemic hypotonic hyponatremia.4,5,42–45

Blockade of AVP binding can occur at one or more of its three distinct AVP receptors: V1, which are predominantly found in the liver, central nervous system, and cardiomyocytes; V2, located in the distal nephron; and V3, which are localized in the anterior pituitary and pancreas. Selective antagonism of the V2 receptor prevents aquaporin-2 water channel transport to the apical surface, thereby decreasing AVP-dependent water reabsorption in the collecting duct. This results in an increase in urine output and free-water excretion along with a decrease in urine osmolality and an increase in serum sodium. These positive outcomes are achieved without significantly increasing the excretion of electrolytes and thus these agents have been called “aquaretics.”44 Convaptan, a mixed vasopressin V1- and V2-receptor antagonist, was approved by the FDA in 2006 for treatment of acute euclidean hyponatremia in hospitalized patients. Because it is available only for intravenous administration and is not approved for use in patients with heart failure, its utility for the treatment of chronic hyponatremia is very limited. Several selective V2 antagonists have been investigated recently and show promise for the treatment of several chronic hyponatremic syndromes.4,42–45

Tolvaptan (Samsca; Otsuka America Pharmaceutical Company, Ltd.) is an orally active selective AVP V2-receptor blocker that received FDA marketing approval in May 2009 for the treatment of clinically significant (serum sodium <125 mEq/L [<125 mmol/L]) euclidean or hypervolemic hyponatremia or less marked symptomatic hyponatremia that has been nonresponsive to other therapeutic interventions in patients with heart failure, cirrhosis, and SIADH.49 It appears to be safe and effective at promoting aquaretics and raising

The serum sodium level should be measured every 24 to 48 hours after the water restriction is initiated until it stabilizes at a concentration of greater than 125 mEq/L (greater than 125 mmol/L). A continued decline in the serum sodium level would indicate either nonadherence to the prescribed restriction or the need for a more stringent restriction. Once the serum sodium level has stabilized above 125 mEq/L (125 mmol/L), patients should then be seen every 2 to 4 weeks to assess neurologic status and to obtain serum and urine for sodium, potassium, and osmolality. Again, attention should be given to volume status (i.e., blood pressure, mucous membranes, skin turgor, and heart and lung examination), particularly in patients who are being treated with sodium chloride tablets and loop diuretics.

## EVALUATION OF THERAPEUTIC OUTCOMES

The initial treatment goals for patients with asymptomatic or minimally symptomatic hypotonic hyponatremia and an expanded ECF volume include achieving a negative water balance while minimizing rapid changes in cell volume until the serum sodium is greater than 125 mEq/L (greater than 125 mmol/L). This entails correction of the underlying cause when possible, as well as restriction of water intake to a volume less than 1,000 to 1,200 mL/day. Dietary intake of sodium should be restricted to 1,000 to 2,000 mg/day, depending on the degree of ECF volume expansion and edema.

Patients with hypervolemic hypotonic hyponatremia caused by congestive heart failure should be treated with measures that can potentially improve cardiac contractility and improve the effective circulating volume, thereby limiting the nonosmotic release of AVP. Therapeutic options include digitalis or afterload reduction with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs). Of these, only ACEIs have been shown in clinical trials to be of benefit in partially correcting hyponatremia in patients with congestive heart failure. No specific ACE inhibitor offers any particular advantage for this indication, and the dose should be titrated to keep the systolic blood pressure in the 110 to 130 mm Hg range. Dose-limiting adverse effects include hyperkalemia (serum potassium >5.5 mEq/L [>5.5 mmol/L]), as well as a decline in renal function. The benefits and risks of continuing ACE inhibition must be weighed carefully in each case, but a decrease

serum sodium levels in both short- and intermediate-term studies (SALT-1 and SALT-2) when given alone. When used alone it is superior to furosemide or fluid restriction and when given in combination synergistic effects have been noted.

Tolvaptan is primarily metabolized by the CYP3A4 and less than 1% is renally eliminated unchanged; thus physicians should avoid its use in those receiving potent inhibitors of CYP3A4 such as ketocazole, clarithromycin, itraconazole, ritonivir, etc. Concomitant therapy with P-gp inhibitors and grapefruit juice has also been noted to result in increased serum concentrations. In contrast, the optimal benefits of tolvaptan therapy may not be realized, and its dosage may need to be increased for those patients who are receiving CYP3A4 inducers such as phenytoin and St. John’s Wort, etc.

Dose linearity has been observed within the therapeutic range and minimal accumulation, as was expected, based on its terminal half-life of 5 to 9 hours after seven plus days of therapy.

Tolvaptan’s recommended starting dosage is 15 mg orally once daily. If, after 24 hours, a greater increase in serum sodium concentration is needed, the dosage may be increased to 30 mg once daily and after another 24 hours, to a maximum of 60 mg once daily. Tolvaptan therapy is contraindicated in those needing rapid correction of their serum sodium concentration, those unable to sense or respond appropriately to thirst, patients with hypovolemic hyponatremia, patients taking strong CYP3A4 inhibitors, and patients who are not excreting urine. Among clinical trial participants who had a serum sodium concentration of less than 125 mEq/L (less than 125 mmol/L) at the start of tolvaptan therapy, the most common adverse events were thirst, dry mouth, weakness, constipation, hyperglycemia, and urinary frequency. Although these adverse events have rarely necessitated discontinuation of therapy, FDA-approved labeling has a boxed warning stating that tolvaptan therapy should begin or resume only in a hospital where clinicians can closely monitor the patient’s serum sodium concentration. The labeling also states that healthcare providers must review the product’s medication guide with every patient receiving tolvaptan therapy.

The vaptans have dramatic effects on water excretion and tolvaptan represents the greatest breakthrough in the therapy of hyponatremia and disorders of fluid homeostasis since the introduction of loop diuretics. The role of vaptans in the clinical management of patients with SIADH, heart failure, and cirrhosis will likely expand as further experience is gained.

It is important to recognize that vasopressin receptor antagonists are contraindicated in hypovolemic patients as their use would worsen the hypovolemia.
in glomerular filtration rate (GFR) of less than 30% that stabilizes within 2 months of therapy initiation generally does not require dosage reduction or discontinuation of the ACE inhibitor.\(^3\)

**CLINICAL CONTROVERSY**

Some clinicians regard any increase in serum creatinine in patients on ACEIs as a reason to decrease dosage or discontinue the medication. ACEIs selectively dilate the afferent arteriole, causing a decrease in intraglomerular pressure and reduced GFR. Although this might be viewed negatively, many experts suggest that the decrease in pressure is likely renoprotective, and that one does not need to reduce the dosage or discontinue therapy unless the resulting decrease in GFR is greater than 30% and does not stabilize within 2 months.

Other potentially treatable causes of asymptomatic hyponatremia associated with an expanded ECF volume include nephrotic syndrome and cirrhosis. ACEIs can be used to decrease proteinuria in patients with nephrotic syndrome, leading to partial correction of hypoalbuminemia and to a decrease in nonosmotic AVP release. Patients with advanced cirrhosis can benefit from placement of a transjugular intrahepatic portosystemic shunt, which can increase the effective circulating volume and thus reduce the nonosmotic release of AVP. This procedure can potentially exacerbate or precipitate hepatic encephalopathy, and should be avoided in patients with a history of encephalopathy.

Vasopressin receptor antagonists have also been proposed for the treatment of hypervolemic hypotonic hyponatremia in patients with congestive heart failure and cirrhosis.\(^3,4,5,6,7\) The effectiveness of tolvaptan in the short-term management of heart failure patients with hypervolemic hyponatremia has been evidenced by decreased body weight, increased urine output, decreased pulmonary capillary wedge pressure, and decreases in urine osmolality.\(^8,9,10\) Long-standing beneficial effects, reduction in hospitalization or death, or progression of heart failure have not been observed in several pivotal trials.\(^5,8,9,10\) Prolonged use of tolvaptan leads to increased endogenous levels of AVP and some have theorized that this over-stimulation of V1A-receptors could lead to increased afterload and progression of HF.\(^10\) However, after 52 weeks of tolvaptan therapy (30 mg daily) no worsening of left ventricular dilatation was observed by Udelson and colleagues.\(^10\)

**EVALUATION OF THERAPEUTIC OUTCOMES**

Patients should initially be evaluated on a daily basis for lung congestion, ascites, peripheral edema, and signs or symptoms of hyponatremia. The serum sodium concentration should be measured daily until it stabilizes above 125 mEq/L (125 mmol/L) following initiation of water restriction. Patients should then be assessed 1 week following discharge, and then every 2 to 4 weeks to assess compliance with the water restriction and other treatment measures, volume status, and hyponatremia-related symptoms.

**HYPERNATREMIA**

**EPIDEMIOLOGY AND ETIOLOGY**

Hypernatremia (serum sodium >145 mEq/L [>145 mmol/L]) is always associated with hypertoncity and results from a deficit of water relative to ECF sodium content.\(^1\) Hyperosmolar states are a potent stimulus for thirst, and therefore hypernatremia is most commonly observed in patients with an impaired thirst response or in those without access to water. Infants and comatose patients, as well as elderly or disabled patients with an impaired sensorium or functional status are therefore at highest risk for this disorder.\(^2\) The incidence of hypernatremia in general medical-surgical hospital patients and intensive care unit patients has been estimated to be at least 1% and 7.9%, respectively.\(^3,4\) Outcome generally depends on the rapidity with which the hypernatremia developed. Mortality from acute hypernatremia in children, which develops in less than 72 hours, ranges from 10% to 70%. In contrast, chronic hypernatremia in children, defined as that which develops over 3 or more days, has a mortality rate of 10%.\(^3,4\) An acute increase in serum sodium in adults to greater than 160 mEq/L (greater than 160 mmol/L) is associated with a 75% mortality rate.\(^3,4\) Adults in whom the hypernatremia developed at a slower rate have a lower but still high mortality rate of approximately 60%. Hypernatremia in adults is often associated with a serious underlying illness, which likely contributes to the high mortality rate.

**PATHOPHYSIOLOGY**

Hypernatremia can result from either loss of water or hypotonic fluids, or less commonly from administration of hypertonic fluids or ingestion of sodium. Patients develop hypovolemic, hypervolemic, or isovolemic hypernatremia depending on the relative magnitude of sodium and water loss or gain caused by the underlying condition (Fig. 58–3).

Water loss commonly occurs as a result of insensible losses (evaporative losses of water through the skin and lungs) in patients deprived of water. Hospitalized patients who are febrile or receiving mechanical ventilation are often treated with intravenous fluids containing insufficient free water to replace insensible losses. Hypernatremia can be observed in patients with hypotonic gastrointestinal losses (diarrhea or vomiting) or in patients who have been exposed to high temperatures who suffer large water losses from both sweat and insensible losses.

Diabetes insipidus (DI) is a condition characterized by decreased AVP secretion or decreased renal response to AVP.\(^5,6,7\) Patients excrete large volumes (3 to 20 L/day) of dilute urine, resulting in large urinary losses of water. DI is classified as either central (decreased AVP secretion) or nephrogenic (decreased renal response to AVP). Table 58–3 summarizes the causes of DI. Patients with central DI often present with sudden onset of polyuria, whereas patients with nephrogenic DI develop polyuria more gradually.

Administration of hypertonic sodium chloride can result in hypernatremia and an expanded ECF volume. This is typically iatrogenic, and can follow administration of sodium bicarbonate, use of hypertonic sodium chloride enemas, or intrauterine injection of hypertonic sodium chloride. Rarely, patients with hyperaldosteronism spontaneously present with an expanded ECF and mild hypernatremia.\(^8\)

CNS, central nervous system; DI, diabetes insipidus.

**CLINICAL PRESENTATION**

The symptoms of hypernatremia are primarily caused by a decrease in neuronal cell volume and include weakness, lethargy, restlessness, irritability, and confusion. Symptoms of more severe or rapidly developing hypernatremia include twitching, seizures, coma, and death. Hypernatremia results in movement of water from the intracellular space to the extracellular fluid. As discussed above, neurons can adapt to ECF tonicity changes by adjusting intracellular osmolality, including decreasing or increasing the concentration of organic osmolytes. In the case of hypernatremia, ECF hypertonicity results in generation of intracellular organic osmolytes within 24 hours of onset. This increase in intracellular fluid tonicity then draws water into the neurons, thus limiting the decrease in cell volume. Patients with chronic hypernatremia are therefore less likely to present with symptoms caused by this cerebral adaptation than patients with acute hypernatremia.

**CLINICAL PRESENTATION OF HYPERNATREMIA**

**General**

- The rise in the plasma sodium concentration and osmolality causes acute water movement from the intracellular to the extracellular fluid. In the brain this decrease in volume can cause rupture of the cerebral veins, leading to focal intracerebral and subarachnoid hemorrhages and possible irreversible neurologic damage.

**Symptoms**

- The clinical manifestations of this disorder begin with lethargy, weakness, confusion, restlessness, and irritability, and can progress to twitching, seizures, coma, and death. Severe symptoms usually require an acute elevation in the plasma sodium concentration to above 160 mEq/L (160 mmol/L). Values >180 mEq/L (>180 mmol/L) are associated with a high mortality rate.

**Signs**

- Signs of hypernatremia can include postural hypotension, tachycardia, dry oral mucosa, decreased skin turgor, and reduced or increased output of dilute or concentrated urine, depending on cause.
- Signs associated with chronic hypernatremia are often difficult to detect because most affected adults have underlying neurologic disease.

**Laboratory Tests**

- Serum sodium levels are generally >145 mEq/L (>145 mmol/L). Measurement of urine volume and osmolality may be helpful in diagnosing the cause.

Hypernatremia is often associated with serious underlying illness, and signs and symptoms related to that illness can also be present. Patients with a history of severe diarrhea or vomiting can present with ECF volume depletion. Elderly patients deprived of water after sustaining a stroke or hip fracture often present with mental status changes and signs of ECF volume depletion. Clinically detectable extracellular fluid volume depletion, however, might not be evident until the serum sodium concentration exceeds 160 mEq/L (160 mmol/L), because these patients primarily have water loss, two thirds of which is derived from the intracellular space. The urine is concentrated, osmolality often exceeds 450 mOsm/kg (450 mmol/kg), as a result of both osmotic and nonosmotic release of AVP. The first step in evaluating patients with hypernatremia is the clinical assessment of the ECF volume, urine volume, and urine osmolality (Fig. 58–4).

Patients with a contracted ECF volume and a low urine output include those who have sustained insensible water losses that exceed intake, as well as those with extrarenal losses of hypotonic fluids. On physical examination, one should search for postural hypotension, diminished skin turgor, and delayed capillary refill. The daily urine output is typically less than 1 L.

A recent multicenter, case-control study examined the clinical presentation of hypernatremia in 150 elderly patients in geriatric care facilities. Low blood pressure, tachycardia, dry oral mucosa, decreased skin turgor, and recent changes in consciousness were all more common in hypernatremic patients than in controls. Perhaps not surprisingly in this mixed patient population, the presence of signs of dehydration was variable, with orthostatic hypotension and decreased subclavicular and forearm skin turgor present in at least 60% of patients. Abnormal subclavicular and thigh skin turgor, dry oral mucosa, and recent change in consciousness were significantly and independently associated with hypernatremia.

**Osmotic Diuresis**

Patients undergoing an osmotic diuresis generally have urine volumes greater than 3 L/day. Excessive urinary excretion of glucose, sodium, urea, or an exogenously administered solute such as mannitol are identified either by history or by direct measurement of serum and urinary concentrations of the suspected solute. Patients with postobstructive diuresis, such as those with bladder outlet obstruction caused by prostatic hypertrophy, are usually volume expanded as a result of retained excess solute because of a decline in the GFR. The osmotic diuresis that follows alleviation of the obstruction is appropriate in that it promotes excretion of the excess retained solute. Patients with severe hyperglycemia, conversely, present with signs of volume depletion, and the diuresis is therefore inappropriate, further exacerbating the degree of ECF volume contraction.

**Diabetes Insipidus**

Patients with DI tend to maintain a normal ECF volume as long as they are conscious and have free access to water. Patients typically have only a slight elevation in the serum sodium concentration (usually in the 141–145 mEq/L [141–145 mmol/L] range), and a daily urine volume greater than 3 L. A water deprivation test is sometimes recommended to aid in the differential diagnosis between central and nephrogenic DI. This consists of depriving patients of water for 8 to 12 hours. Urine osmolality, urine volume, and body weight are then measured before and after subcutaneous administration of 5 mcg of desmopressin acetate. Patients with central DI will show a prompt increase in urine osmolality to approximately 600 mOsm/kg (600 mmol/kg) and a decrease in urine volume after desmopressin administration. Those with nephrogenic DI will be unable to increase the urine osmolality above 300 mOsm/kg (300 mmol/kg). The direct measurement of
vasopressin levels after infusion of 5% sodium chloride at a rate of 0.05 mL/kg/min for no more than 2 hours improves the accuracy of diagnosis, but carries a high risk of ECF volume overload.²²

The value of performing a water deprivation test in patients with polyuria and hypernatremia, such as patients with DI, has recently been questioned.²² Because hypernatremia provides a maximal stimulus for AVP secretion, discriminating between nephrogenic and central DI can be based on plasma vasopressin concentration and urinary response to desmopressin without the need for water deprivation. The water deprivation test is thus likely to only be of diagnostic value in patients with polyuria and a normal serum sodium concentration.

Sodium Overload

Patients who have ingested large amounts of sodium (>4 tablespoons [1,400 mEq or 1,400 mmol Na⁺] of sodium chloride) or who have received greater than 5 L of hypertonic fluids are volume expanded, although this may not always be clinically evident as edema. This results in an osmotic diuresis, polyuria, and a urine osmolality greater than 300 mOsm/kg (greater than 300 mmol/kg). The excess sodium will be excreted in the urine in patients with normal renal function.

PHARMACOLOGIC THERAPY

Hypovolemic Hypernatremia

Hypovolemic hypernatremia should initially be treated with 0.9% sodium chloride until hemodynamic stability is restored. An initial infusion rate of 200 to 300 mL/h will likely be appropriate for many patients. Once intravascular volume is restored, 0.45% sodium chloride or 5% dextrose in water can then be infused to correct the water deficit,³⁰ the volume of which can be estimated as:

Water deficit = Present TBW × [(S₁Na/140) − 1]

where TBW = total body water; S₁Na = initial patient serum sodium concentration (in mEq/L [or mmol/L]); and 140 = normal or goal S₁Na (in mEq/L [or mmol/L]).

The rate of correction depends on the rapidity with which the hypernatremia developed. Hypernatremia that has developed over a few hours can be initially corrected at a rate of approximately 1 mEq/L (1 mmol/L) per hour, whereas a rate of 0.5 mEq/L (0.5 mmol/L) per hour should be used when it has developed more slowly.²⁰,²⁴ The rate of correction should generally be limited to no more than 10 mEq/L (10 mmol/L) per day.²⁰,²⁴

Treatment of hyperglycemia-induced osmotic diuresis consists of correcting the hyperglycemia with insulin, as well as administering 0.9% sodium chloride until signs of ECF volume depletion resolve. Once hemodynamic stability is restored, the water deficit should be corrected in a manner analogous to that described for patients with hypovolemic hypernatremia above. The corrected serum sodium level should be calculated by adding 1.7 mEq/L (1.7 mmol/L) for every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration before estimating the water deficit.³

Hypernatremia in patients undergoing a postobstructive diuresis should be treated with infusion of hypotonic fluids such as 0.45% sodium chloride at maintenance rates of approximately 1.5 mL/kg per hour. It is important to avoid the temptation to administer fluids to replace urine output on a 1:1 volume basis, because this tends to perpetuate the diuresis.

The serum sodium concentration and fluid status should be monitored every 2 to 3 hours over the first 24 hours of admission in patients with symptomatic hypernatremia to permit appropriate adjustment in the rate of infusion of hypotonic fluids. After

TREATMENT

Hypernatremia

DESIRED OUTCOME

The desired goals for patients with hypernatremia include correction of the serum sodium concentration at a rate that restores and maintains cell volume as close to normal as possible, as well as normalizing the ECF volume in states of ECF volume depletion or expansion. Adequate treatment should result in the resolution of symptoms associated with hypovolemia. Careful titration of fluids and medications should minimize the adverse effects from too rapid correction. Rapid correction can result in movement of excessive water into the brain cells, resulting in cerebral edema, seizures, neurologic damage, and potentially death.¹ Modulation of dietary sodium intake and sodium replacement can be necessary to prevent recurrence of hypernatremia.

Symptoms resolve and the serum sodium is less than 148 mEq/L (less than 148 mmol/L), serum sodium determinations every 6 to 12 hours and fluid status assessment every 8 to 24 hours are generally sufficient to follow the course of therapy.

Central Diabetes Insipidus

Patients with central DI should generally receive AVP replacement therapy with desmopressin, an AVP analog. Because of variable absorption of oral desmopressin, DI is best treated with the intranasal formulation 1-desamino-8-D-arginine vasopressin (DDAVP); however, oral tablets are available and can be useful in some patients. The beginning intranasal dose should be 10 mcg once daily. Ultimately, the dose may need to be titrated up to 10 mcg twice daily for most adults. Each insufflation of intranasal DDAVP delivers 10 mcg of desmopressin acetate at a concentration of 100 mcg/mL. Several medications with antidiuretic proper-
ties have been used successfully in the management of central and nephrogenic DI (Table 58–4). They can be used as an alternative to DDAVP or adjunctively.

The desmopressin dose should be adjusted to achieve adequate urinary concentration during sleep to prevent nocturia, to result in a daily urine volume of approximately 1.5 to 2 L, and to maintain the serum sodium concentration in the 137 to 142 mEq/L (137–142 mmol/L) range. The serum sodium concentration should be measured every 3 to 4 days during the initial dose titration period, and then every 2 to 4 months. Administration of desmopressin results in nonsuppressible AVP activity and presents a risk of water intoxication caused by excess water retention. Patients using desmopressin should therefore be monitored for signs and symptoms of hyponatremia and hypervolemia. It has been suggested that patients using desmopressin who experience water intoxication can minimize the risk of a second episode by delaying a dose of desmopressin each week until polyuria and thirst develop, thus demonstrating the need for additional desmopressin doses.

Nephrogenic Diabetes Insipidus

Hypercalcemia and hypokalemia should be corrected, and medications that contribute to the pathogenesis should be discontinued. One key goal in treating nephrogenic DI is to induce a mild ECFVd of 1–1.5 L with a thiazide diuretic and dietary sodium restriction (85 mEq [85 mmol] Na+ or 2,000 mg sodium chloride per day), which often can decrease urine volume by as much as 50% (see Table 58–4). This will increase proximal water reabsorption, decrease the volume of filtrate delivered to the distal nephron, and decrease urine volume. NSAIDs such as indomethacin at a dose of 50 mg 3 times a day can potentiate the activity of AVP and can be used as adjunctive therapy. Patients with lithium-induced nephrogenic DI can derive particular benefit from amiloride at a dose of 5 to 10 mg daily; amiloride directly inhibits uptake of lithium from the tubular lumen into principal cells in the cortical collecting duct.

EVALUATION OF TREATMENT OUTCOMES

Physical examination with attention to volume status and measurement of serum and urine sodium concentration and osmolality should be assessed every 2 to 3 months during chronic therapy. A 24-hour urine collection to measure urine volume and sodium excretion will help guide therapy with diuretics and determine adherence to sodium restriction.

Sodium Overload

Treatment of sodium overload consists of administration of loop diuretics to facilitate excretion of the excess sodium, as well as intravenous D,W. The latter should be infused at a rate that will decrease the serum sodium at approximately 0.5 mEq/L (0.5 mmol/L) per hour, or 1 mEq/L (1 mmol/L) per hour in cases in which the hypernatremia developed rapidly over several hours. The volume of infusate may be estimated as described previously. Furosemide should be administered at a dose of 20 to 40 mg intravenously every 6 hours.

The serum sodium should initially be measured every 2 to 4 hours, and the diuretic continued until signs of ECF volume overload (pulmonary congestion and edema) resolve. The serum sodium concentration can be determined every 6 to 12 hours once the serum sodium level is less than 148 mEq/L (less than 148 mmol/L) and symptoms of hypertonicity resolve.

Edema may be defined as a clinically detectable increase in interstitial fluid volume. Clinical detectability in adults generally requires an interstitial volume increase of at least 2.5 to 3 L. Edema develops when excess sodium is retained either as a primary defect in renal sodium excretion, or as a response to a decrease in the effective circulating volume despite a normal or expanded ECF volume. An increase in the capillary hydrostatic pressure because of

PATHOPHYSIOLOGY
an expansion of the ECF volume, or an increase in central venous pressure may lead to edema formation. Edema may also occur when there is an alteration in Starling forces within the capillary. 77 The Starling equation denotes the relationship between factors affecting the movement of fluid between the capillary and interstitium and is discussed in detail in Chapter 30.

Edema may develop rapidly in those with an acute decompensation in myocardial contractility which leads to an elevation in pulmonary venous pressure that is transmitted back to the pulmonary capillaries and ultimatley results in acute pulmonary edema. Edema may also develop insidiously as in the case of renal sodium and water retention due to diminished effective circulating volume which leads to a rise in the ECF volume and edema formation in both peripheral and pulmonary interstitial tissues.

Edema formation in patients with nephrotic syndrome is primarily related to renal sodium and water retention. A decrease in capillary oncotic pressure does not appear to play a major role until the serum albumin concentration less than 2 g/dL (less than 20 g/L). This is explained by the fact that both capillary and interstitial oncotic pressure decrease proportionately above a serum albumin concentration of 2 g/dL (20 g/L), and thus the transcapillary oncotic gradient is not significantly altered. 79

Patients with cirrhosis initially develop ascites as a result of an increase in the pressure in the portal circulation proximal to the diseased liver. Sequestration of fluid in the abdominal cavity (ascites) and peripheral vasodilation as a consequence of increased levels of circulating cytokines, result in a decrease in the effective circulating volume, activation of the sympathetic nervous system, and secondary hyperaldosteronism. Therefore, renal sodium retention leads to worsened ascites and edema.

### CLINICAL PRESENTATION

Edema is usually first detected in the feet or pretibial area of ambulatory patients and in the presacral area of bed-bound individuals. Edema is described as “pitting” when a depression created by exerting pressure for several seconds over a bony prominence such as the tibia does not rapidly refill. The severity of the edema should be rated on a semi-quantitative scale of 1+ to 4+ depending on the depth of the pit (1+ = 2 mm, 2+ = 4 mm, 3+ = 6 mm, and 4+ = 8 mm).

The extent of the edema should also be quantified according to the area of involvement. Pretibial edema, for example, should be quantified according to how far it extends up the lower leg (e.g., one-third up the lower leg). Pulmonary edema, an increase in lung interstitial and alveolar water, is often evidenced by crackles (also called rales) upon auscultation. It should be quantified according to how far the crackles extend from the dependent portion of the lung(s). So, for example, edema limited to the ankles and feet would indicate less severe edema than edema that extends halfway up the lower legs, and crackles limited to the base of both lungs in an upright person would indicate less severe pulmonary edema than crackles throughout both lung fields.

### TREATMENT

#### Edema

**GENERAL APPROACH TO TREATMENT**

The goals of therapy are to minimize tissue edema and thus improve organ function, as well as to relieve symptoms of edema such as dyspnea in patients with CHF or abdominal distention in patients with ascites. It is important to emphasize that the presence of edema does not always dictate the need for instituting pharmacologic (diuretic) therapy. Only pulmonary edema requires immediate pharmacologic treatment because it is life-threatening. Other forms of edema may be treated gradually, with a comprehensive approach that includes not only diuretics, but also sodium restriction and treatment of the underlying disease state. Sodium intake should generally be restricted to 1,000 to 2,000 mg/day. A slow, more judicious approach in non-life-threatening situations will help to minimize complications of diuretic therapy and excessive fluid removal. These may include impaired vital organ perfusion, azotemia, and impaired cardiac output due to a fall in the left ventricular end-diastolic filling pressure.

**PHARMACOLOGIC THERAPY**

Diuretics are the primary pharmacologic therapy for the management of edema. Patients with expanded ECF volume and edema often require therapy with diuretics when treatment of the underlying disease and daily sodium restriction are insufficient to relieve the edema. Diuretics can be categorized according to the site in the nephron where sodium reabsorption is inhibited. Loop diuretics inhibit the sodium-potassium-chloride (Na⁺-K⁺-2Cl⁻) carrier in the loop of Henle. Thiazide diuretics inhibit the Na⁺-Cl⁻ carrier in the distal tubule. Finally, potassium-sparing diuretics inhibit the sodium channel in the cortical collecting duct either directly (tri-amterene and amiloride), or by interfering with aldosterone activity (spironolactone and eplerenone). The efficacy of a diuretic depends on the presence of several factors, including the amount of filtered solute normally reabsorbed at the site of action, the amount of solute reabsorbed distal to the site of action, and adequate delivery of drug to the site of action in the nephron.

Loop diuretics are the most potent diuretics, as evidenced by the fact that they increase peak fractional excretion of sodium (FeNa) to 20% to 25% (0.20–0.25). Thiazide- and potassium-sparing diuretics are less potent and increase peak FeNa to 3% to 5% (0.03–0.05) and 1% to 2% (0.01–0.02), respectively. 1 Although

| TABLE 58-5 Maximal Effective Dose and Dosing Interval for Edema Management with Loop Diuretics |

CHF, congestive heart failure; GFR, glomerular filtration rate.
a large portion of the filtered sodium is reabsorbed in the proximal nephron, the efficacy of proximal-acting diuretics such as acetazolamide is limited by reabsorption of the excess fluid and sodium in the loop of Henle.

The effectiveness of thiazide and loop diuretics is dependent on the concentration of the drug in the tubular lumen. These diuretics are delivered to the tubular lumen of the kidney by active transport by the proximal tubular cells. Osmotic diuretics, conversely, are freely filtered into the tubular lumen in the proximal tubule, whereas spironolactone gains access to mineralocorticoid receptors in the cortical collecting duct through diffusion from the systemic circulation.

A threshold concentration of loop or thiazide diuretic must be delivered to the active site (e.g., loop of Henle or distal tubule) to achieve a natriuresis. Once this concentration is achieved, further increases in diuretic dose will not elicit an increase in diuretic response. Thus a ceiling dose of these diuretics is recognized. Administration of 40 mg of intravenous furosemide to a normal subject will result in excretion of 200 to 250 mEq (200–250 mmol) of sodium in 3 to 4 L of urine over a 3- to 4-hour period. Table 58–5 summarizes the maximal effective doses and dosing intervals for loop diuretics in patients with cirrhosis, CHF, nephrotic syndrome, as well as those with reduced renal function.

Patients with renal insufficiency often require larger doses of diuretics to achieve adequate concentrations of the drug at the active site. The natriuretic response is decreased in patients with renal insufficiency because the filtered load of sodium falls proportionately as GFR declines. This can be partially overcome by dosing diuretics more frequently, as well as by using continuous infusions in critically ill hospitalized patients. The latter will maintain more consistent levels of the diuretic above the threshold concentration. Patients who are diuretic resistant should be treated with both a loop and a thiazide-type diuretic. Patients with CHF and a normal GFR may have impaired oral absorption of furosemide. An adequate diuresis is most readily sustained by increasing the frequency of diuretic administration.

Diuretic resistance can be caused by increased uptake of sodium in the distal tubule, impaired delivery of diuretics to the site of action, or decreased intrinsic diuretic activity. Animal studies have demonstrated binding of furosemide to albumin in the tubular lumen, which decreases the availability of the drug to the active site. Human studies, however, have demonstrated that when albumin binding is inhibited by concurrent administration of sulfasoxazole, diuretic resistance persists, suggesting a decrease in intrinsic tubular sensitivity to loop diuretics. This impaired natriuretic response can be overcome by using higher diuretic doses to increase the delivery of free drug to the secretory site in the nephron. Combinations of loop diuretics with distally acting diuretics are generally necessary to promote a natriuresis that exceeds tubular sodium reabsorption for those with nephrotic syndrome.

Secondary hyperaldosteronism plays a major role in the pathogenesis of edema in patients with cirrhosis. Therefore, these patients should initially be treated with spironolactone in the absence of impaired GFR and hyperkalemia. Thiazides can then be added for patients with a creatinine clearance >50 mL/min (>0.84 mL/s). For those patients who remain diuretic resistant, a loop diuretic can replace the thiazide. Patients with impaired GFR (creatinine clearance of <40 mL/min [<0.67 mL/s]) can require a loop diuretic, with addition of a thiazide in those who do not achieve adequate diuresis. Care should be taken to avoid hypokalemia, which can precipitate hepatic encephalopathy by increasing ammoniagenesis.

Complications of loop and thiazide diuretic therapy include hypokalemia, excess depletion of ECF volume, hyponatremia, hypomagnesemia, metabolic alkalosis, and hyperuricemia. Thiazides can also cause hypercalcemia, particularly in patients with mild subclinical hyperparathyroidism. Chronic therapy with potassium-sparing diuretics, including triamterene, amiloride, and spironolactone, can cause a mild metabolic acidosis and can precipitate hyperkalemia. Patients with moderate to severe kidney dysfunction or those receiving NSAIDs, ACEIs, or ARBs are

**FIGURE 58-6.** Therapeutic algorithm for diuretic therapy in patients with nephrotic syndrome. Albumin concentration of 2 gm/dL is equivalent to 20 g/L (HCTZ, hydrochlorothiazide.)

**FIGURE 58-5.** Therapeutic algorithm for diuretic use in patients with congestive heart failure. (GFR, glomerular filtration rate [50 mL/min is equivalent to 0.84 mL/s]; HCTZ, hydrochlorothiazide.)

**CLINICAL CONTROVERSY**

Some clinicians advocate using combinations of diuretics in cases of diuretic resistance associated with nephrotic syndrome, while others prefer to use larger-than-average doses of single agents to overcome enhanced protein binding in the tubular lumen associated with proteinuria.
FIGURE 58-7. Therapeutic algorithm for diuretic use in patients with cirrhosis. (CLc, creatinine clearance [50 mL/min is equivalent to 0.84 mL/s]; HCTZ, hydrochlorothiazide.)

at highest risk for this complication. In addition, spironolactone can cause reversible gynecomastia in patients receiving therapy for more than several weeks. This side effect, however, has not been associated with eplerenone, a newly available aldosterone antagonist.65

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored by careful history and intermittent physical examinations to detect signs and symptoms of edema as well as adverse effects of treatment. Physical examination should include measurement of blood pressure and pulse in either supine or seated positions and after standing for 2 to 3 minutes. ECF volume can be estimated based on the height of the jugular venous pressure, extent of edema, auscultation of the heart and lungs, and skin mobility. Followup monitoring (10–14 days after initiation of therapy) should include determinations of serum sodium, potassium, chloride, bicarbonate, magnesium, calcium, BUN, serum creatinine, and uric acid. A new steady state will have developed over that time period and further fluctuations in ECF volume and electrolyte balance should not occur in the absence of a change in clinical status, diuretic dose, or dietary intake. Repeated blood tests are not necessary at every visit unless there is a change in the patient’s clinical status.

Disorders of calcium and phosphorus are common complications of multiple acute and chronic diseases. These disorders are frequently seen in the acute care setting; however, they are also often present in ambulatory patients, usually in a less severe state. The consequences of electrolyte disorders can range from asymptomatic to life-threatening, requiring hospitalization and emergent treatment. The maintenance of fluid and electrolyte homeostasis requires adequate functioning and modulation by multiple hormones on tissues of multiple organ systems.

There are many common drug therapies that can disturb the normal homeostatic mechanisms that maintain calcium and phosphorous balance. In addition, with some drug therapies, toxicity is enhanced when underlying electrolyte disorders are present. Drug-induced disorders typically respond well to discontinuation of the offending agent(s); however, additional therapies are sometimes required to correct the disorder. This chapter reviews the etiology, classification, clinical presentation, and therapy for the most common disorders of calcium and phosphorus homeostasis.

**DISORDERS OF CALCIUM HOMEOSTASIS**

The maintenance of physiologic calcium concentrations in the intracellular and extracellular spaces is vital for the preservation and function of cell membranes; propagation of neuromuscular activity; regulation of endocrine and exocrine secretory functions; blood coagulation cascade; platelet adhesion process; bone metabolism; muscle cell excitation/contraction coupling; and mediation of the electrophysiologic slow-channel response in cardiac and smooth-muscle tissue.

The disorders of calcium homeostasis are related to the calcium content of the extracellular fluid, which is tightly regulated and comprises less than 0.5% of the total body stores of calcium. Skeletal bone contains more than 99% of total body stores of calcium. Extracellular fluid (ECF) calcium is moderately bound to plasma proteins (46%), primarily albumin. Ionized or free calcium is the physiologically active form and is the fraction that is homeostatically regulated. Extracellular calcium, however, is most commonly measured as the total serum calcium level, which includes both bound and unbound calcium. The normal total serum calcium concentration range is 8.5 to 10.5 mg/dL (2.13–2.63 mmol/L).

Proper assessment of total serum calcium concentrations includes measurement of the patient’s serum albumin concentration. Hypoalbuminemia, which can be associated with many chronic disease states, is probably the most common cause of “laboratory hypocalcemia.” Patients remain asymptomatic because the unbound or ionized fraction of serum calcium remains normal (normal range, 4.4–5.4 mg/dL [1.10–1.35 mmol/L]). A corrected total serum calcium ($S_{ca}$) concentration can be calculated based on the measured total serum calcium and the difference between a patient’s measured albumin concentration and the normative value of 4 g/dL (40 g/L) by the following equations:

Corrected $S_{ca}$ (mg/dL) = measured $S_{ca}$ (mg/dL) +
\[0.8 \times (4.0 \text{ g/dL} – \text{measured albumin (g/dL)})\]

Or

Corrected $S_{ca}$ (mmol/L) = measured $S_{ca}$ (mmol/L) +
\[0.02 \times (40 \text{ g/L} – \text{measured albumin (g/L)})\]

The concentration of ionized calcium is closely regulated by the interactions of parathyroid hormone (PTH), phosphorus,
vitamin D, and calcitonin (Fig. 59–1). PTH increases serum calcium concentrations by stimulating calcium release from bone, increasing renal tubular reabsorption, and enhancing absorption in the gastrointestinal tract secondary to increased renal production of 1,25-dihydroxy vitamin D₃. Vitamin D directly increases serum calcium, as well as phosphorus concentrations, by increasing gastrointestinal absorption. Indirectly, it can also lead to calcium release from bone and reduced renal excretion. Calcitonin inhibits osteoclastic bone resorption. Its plasma concentrations are increased when ionized calcium concentrations are high as the body attempts to return the calcium level to the normal range. Disruption of these homeostatic mechanisms results in the clinical manifestations of hypercalcemia or hypocalcemia.

Alteration of the concentration of albumin or its binding of calcium can be expected to change the unbound fraction of total serum calcium. The most significant cause of changes in calcium binding to albumin is a change in extracellular fluid pH. In the presence of acute metabolic alkalosis the fraction of calcium bound to albumin is increased, thus reducing the plasma concentration of ionized calcium. This can result in symptomatic hypocalcemia; that is, paresthesia, muscle cramping and spasms, memory loss, and seizures. Conversely, metabolic acidosis decreases calcium binding to albumin and results in increased ionized calcium. Hypoalbuminemic states are probably the most common cause of “laboratory hypocalcemia.” When the albumin level is decreased, the ionized calcium concentration can be normal although total serum calcium concentration is low. Each 1 g/dL (10 g/L) drop in the serum albumin concentration below 4 g/dL (40 g/L) will result in a decrease of total serum calcium concentration by 0.8 mg/dL (0.20 mmol/L). This approach of calculating an albumin-adjusted calcium concentration has been found to overestimate the degree of hypercalcemia and usually fails to identify hypocalcemia in critically ill patients, therefore ionized calcium values should be used to assess calcium status in these patients.

### PATHOPHYSIOLOGY

Hypercalcemia is the result of one or a combination of three primary mechanisms: increased bone resorption, increased gastrointestinal absorption, or increased tubular reabsorption by the kidneys (see Fig. 59–1).

Many tumors secrete PTH–related protein (PTHrP), which binds to the PTH receptors in bone and renal tissues, leading to increased bone resorption and renal tubular reabsorption. Tumors can also secrete substances such as vitamin D, transforming growth factor, interleukins, prostaglandins, interferon, tumor necrosis factor, and granulocyte-macrophage colony-stimulating factor, which are associated with the development of hypercalcemia. Hypercalcemia of malignancy is a common complication of squamous cell carcinomas of the lung, head, and neck, hematologic malignancies such as multiple myeloma and

### HYPERCALCEMIA

There are multiple and diverse causes of hypercalcemia (total serum calcium >10.5 mg/dL [2.62 mmol/L]) (Table 59–1). The most common causes of hypercalcemia are cancer and primary hyperparathyroidism. The reported incidence of primary hyperparathyroidism in the United States ranges from 10 to 30 cases per 100,000 people. Hypercalcemia of cancer occurs in approximately 20% to 40% of cancer patients at some time during the course of their disease. Cancer-associated hypercalcemia is predominantly encountered in hospitalized patients, whereas primary hyperparathyroidism accounts for the vast majority of cases in the outpatient setting.

![Figure 59-1](image-url) Homeostatic mechanisms to maintain serum calcium concentrations.
T-cell lymphomas, and carcinomas of ovary, kidney, bladder, and breast. The most frequent types of malignancy associated with hypercalcemia are carcinomas of the lung and breast. Breast and squamous cell lung carcinomas secrete PTHrP which binds to the type I PTH receptor (PTHr1) and enhances bone resorption. In contrast, up to 40% of patients with multiple myeloma develop hypercalcemia principally as the result of osteoclast-mediated bone destruction. Other causes of chronic hypercalcemia include medications, endocrine and granulomatous disorders, physical immobilization, high bone-turnover states (adolescence and Paget disease), and rhabdomyolysis. Increased gastrointestinal absorption can be the result of excessive ingestion of vitamin D analogs, calcium supplements, and lithium. Lithium and vitamin A therapy can increase bone resorption, whereas increased renal tubular resorption of calcium can occur with thiazide and lithium therapy. The exact mechanism of lithium-induced hypercalcemia is not known but may include competitive inhibition of calcium influx into cells, increasing the threshold sensitivity of the calcium-sensing receptor and subsequent inhibition of PTH gene transcription. Addison’s disease, acromegaly, and thyrotoxicosis are endocrine disorders that can lead to hypercalcemia because of increased renal tubular reabsorption and increased bone resorption. Finally, the granulomatous disorders (sarcoidosis, tuberculosis, histoplasmosis, and leprosy) are associated with hypercalcemia caused by an increase in gastrointestinal and renal tubular absorption secondary to granuloma production of 1,25-dihydroxy vitamin D₃. Milk-alkali syndrome is the term applied to those situations where an individual develops hypercalcemia following the ingestion of calcium and absorbable alkali (e.g., calcium carbonate) and is an important cause of hypercalcemia in patients who are not on dialysis.

### CLINICAL PRESENTATION

Patients with mild to moderate hypercalcemia, that is, total serum calcium concentrations above the upper threshold of normal but less than 13 mg/dL (<3.25 mmol/L) or ionized calcium concentrations less than 6.0 mg/dL (<1.50 mmol/L), can often be asymptomatic. This is typically the case for the vast majority of patients who have drug-induced hypercalcemia or primary hyperparathyroidism. In fact, one study noted normocalcemia in approximately 20% of patients with a diagnosis of primary hyperparathyroidism, suggesting target tissue resistance to PTH. The presenting signs and symptoms of severe hypercalcemia that occur if the total serum calcium concentration is >13 mg/dL (>3.25 mmol/L) may differ depending on the acuity of onset. Hypercalcemia of malignancy usually develops quickly and is accompanied by a classic symptom complex of anorexia, nausea and vomiting, constipation, polyuria, polydipsia, and nocturia. Polyuria and nocturia secondary to a urinary-concentrating defect constitute some of the most frequent renal effects of hypercalcemia. Hypercalcemic crisis is characterized by an acute elevation of total serum calcium to a value >15 mg/dL (>3.75 mmol/L), acute renal insufficiency, and obtundation (inability to arouse). If untreated, hypercalcemic crisis can progress to oliguric renal failure, coma, and life-threatening ventricular arrhythmias. The primary complications associated with chronic hypercalcemia (hyperparathyroidism) include metastatic calcification, hypercalcuria, and chronic renal insufficiency secondary to interstitial nephrocalcinosis.

### CLINICAL PRESENTATION OF HYPERCALCEMIA

#### General

- The signs and symptoms of hypercalcemia depend on severity and on the rapidity of onset.

#### Symptoms

- **Symptoms include fatigue, weakness, anorexia, depression, anxiety, cognitive dysfunction, vague abdominal pain, and constipation.** Renal symptoms can include polyuria, polydipsia, and nocturia. Rarely, severe hypercalcemia leads to acute pancreatitis.

#### Signs

- **Renal:** The most important renal manifestations which are generally the result of chronic hypercalcemia are nephrolithiasis, renal tubular dysfunction, particularly decreased concentrating ability; and acute and chronic renal insufficiency.

- **Cardiovascular:** Long-standing hypercalcemia can lead to the deposition of calcium in heart valves, coronary arteries, and myocardial fibers. Hypercalcemia also directly shortens the myocardial action potential, which is reflected in a shortened QT interval and coving of the ST-T wave. Spontaneous ventricular tachyarrhythmias and elevations in blood pressure have also been reported.

- **Musculoskeletal:** A number of rheumatologic complaints have been described in hyperparathyroidism, including gout, pseudo-gout, and chondrocalcinosis. The relative roles of hypercalcemia and PTH excess in these problems are not known.

#### Laboratory Tests

- **Serum calcium concentrations of >10.5 mg/dL (>2.63 mmol/L) are considered to represent hypercalcemia.** Patients with values up to 13 mg/dL (3.25 mmol/L) are generally considered to have mild or moderate hypercalcemia, whereas those with values greater than this indicate the presence of severe hypercalcemia.

Calcium and/or calcium-phosphorus complex deposition in blood vessels and multiple organs is a complication of chronic hypercalcemia and/or concomitant hyperphosphatemia and hyperparathyroidism. Calcium deposits in atherosclerotic lesions contribute to cardiac disease. Intracardiac and arterial calcifications have been found in patients with Paget disease who have normal renal function. It is hypothesized that similar calcification processes occur in both bone and vascular tissue, leading to cardiovascular diseases including heart failure, systolic hypertension, and ischemic heart disease.

The electrocardiographic changes associated with hypercalcemia include shortening of the QT interval and coving of the ST-T wave. Very high serum calcium concentrations can cause T-wave widening, indicating a repolarization defect that may be associated with spontaneous ventricular tachyarrhythmias. Hypertension and arrhythmias have occurred in the setting of hypercalcemia. The effects of digoxin on cardiac conduction including lowering of the excitation threshold, shortening of the effective refractory period and increased atriointricular refractoriness, can be potentiated by hypercalcemia.

Nephrolithiasis (kidney stones) and nephrocalcinosis (calcium deposits in the kidney) are the primary renal complications arising from long-standing hypercalcemia, as the result of primary hyperparathyroidism. Stone formation is dependent on
a favorable milieu within the kidney or urinary tract such as, oversaturation of the urine and/or reduced concentrations of endogenous inhibitors of crystal formation (e.g., citrate or pyrophosphate). It is estimated that hyperparathyroidism accounts for 2% to 8% of all patients with calcium stones. Of note, in those patients with low glomerular filtration rates (GFRs), the 24-hour urinary calcium will actually diminish secondary to decreased production of 1,25-dihydroxy vitamin D. However, the fractional excretion of calcium might increase. Sarcoïdosis is the other hypercalcemic condition frequently associated with calcium stones. Other causes of nephrolithiasis with calcium-containing stones include hypocitraturia, renal tubular acidosis, hyperoxaluria, and hyperuricosuria. Stone formers who have primary hyperparathyroidism are more likely to be female, older than 50 years of age, and have a family history of multiple endocrine disorders. High dietary sodium intake can also raise urinary calcium concentrations, perhaps due to a reduction in calcium reabsorption in the kidney, thus predisposing patients to calcium stones. Although chronic renal failure can be the ultimate result of persistent stones, it is the primary cause of renal disease in <2% of the end-stage renal disease population.

**TREATMENT**

### Hypercalcemia

#### DESIRED OUTCOME

The indications for the treatment of acute hypercalcemia are dependent on the severity of hypercalcemia, acuity of its development, and presence or absence of symptoms requiring emergent treatment (e.g., necrotizing pancreatitis). The therapeutic intervention plan should be crafted to reverse signs and symptoms, restore normocalcemia, and correct or manage the underlying cause of hypercalcemia.

Chronic hypercalcemia is usually caused by an underlying medical condition or prescribed pharmacotherapies that can be resolved by successful treatment of the condition or withdrawal of the offending agent. Acute hypercalcemic episodes induced by malignancies may be mitigated by chemotherapy and/or radiation treatment. Effective surgical or drug treatment of primary hyperparathyroidism should reduce serum calcium concentrations as well as reduce the development of long-term complications such as vascular complications, chronic kidney disease (CKD), and kidney stones.

#### NONPHARMACOLOGIC THERAPY

Hypercalcemic crisis and acute symptomatic severe hypercalcemia should be considered medical emergencies and treated immediately (Fig. 59–2).

These patients may require immediate-acting interventions to promptly reduce the serum calcium concentration if they are experiencing ECG changes, neurologic manifestations, or pancreatitis. Pharmacologic therapy consisting of volume expansion and enhancement of urinary calcium excretion with loop diuretics is usually the initial management strategy. Hemodialysis against a zero- or low-calcium dialysate solution should be considered for patients with severely impaired renal function (CKD stage 4 or 5) who cannot tolerate large fluid loads and in whom diuretics have limited efficacy.

Effective treatment of moderate to severe hypercalcemia in the absence of life-threatening symptoms begins with attention to the underlying disorder and correction of associated fluid and electrolyte abnormalities. Patients with primary hyperparathyroidism may require surgery, particularly if they have systemic manifestations. Patients with malignancy often require surgical or chemotherapeutic reduction of tumor load to control the exogenous supply of cytokines and hormones (e.g., PTHrP) that cause hypercalcemia. In contrast, patients with drug-induced hypercalcemia generally respond to discontinuation of the offending agent.

---

PHARMACOLOGIC THERAPY

Although dialysis is the most effective method for rapidly reducing highly elevated serum calcium in patients with CKD, many clinicians choose normal saline and/or a loop diuretic approach as the initial therapy.

For those patients with normal to moderately impaired renal function (CKD stages 3 and 4), the cornerstone of initial treatment of severe hypercalcemia or hypercalcemic crisis is volume expansion with normal saline to increase natriuresis and ultimately urinary calcium excretion (see Table 59–2). Patients with symptomatic hypercalcemia are often extracellular volume depleted secondary to vomiting and polyuria; thus rehydration with saline-containing fluids is necessary to interrupt the stimulus for sodium and calcium reabsorption in the renal tubule. Rehydration can be accomplished by the infusion of normal saline at rates of 200 to 300 mL/h, until the patient is fluid resuscitated and serum calcium approaches the upper limit of the normal range. The precise rate depends on concomitant conditions (primarily cardiovascular and renal) and magnitude of hypercalcemia. The saline infusion rate can be decreased to a rate that approximates the patient’s intake of oral or intravenous fluids. (See Chapter 58 for a thorough discussion of the concepts and calculations of water deficit.) Adequacy of hydration is assessed by measuring fluid intake and output or by central venous pressure monitoring. Loop diuretics such as furosemide (40–80 mg IV every 1–4 hours) or ethacrynic acid (for patients with sulfa allergies) can also be instituted to increase urinary calcium excretion and to minimize the development of volume overload from the administration of saline (Fig. 59–2 and Table 59–2). Loop diuretics such as furosemide block calcium (and sodium) reabsorption in the thick ascending limb of the loop of Henle and augment the calciuric effect of saline alone. The importance of rehydration prior to loop diuretic use is critical because if dehydration persists or becomes worse the serum calcium can actually increase because of enhanced proximal tubule calcium reabsorption. Potassium chloride, 10 to 20 mEq/L (10–20 mmol/L), should be added to the saline solution after rehydration is accomplished to maintain normokalemia in the presence of diuretic therapy. Serum magnesium levels should also be monitored, and magnesium replacement instituted if magnesium levels fall below 1.8 mg/dL (0.74 mmol/L). Rehydration with saline and administration of furosemide can result in a decrease of 2 to 3 mg/dL (0.50–0.75 mmol/L) in total serum calcium within 24 to 48 hours.

In those patients in whom saline hydration therapy is contraindicated (e.g., those with severe chronic heart failure [CHF] or moderate to severe renal dysfunction), short-term therapy with calcitonin is a viable alternative agent to initiate reduction of serum calcium levels within 24 to 48 hours. Calcitonin has a rapid onset of action (within 1–2 hours); however, the degree and extent of serum calcium level reduction are often unpredictable. Calcitonin decreases serum calcium concentrations, primarily by inhibiting bone resorption. It can also reduce renal tubular reabsorption of calcium, thus promoting calcitresis. Recently, the calcitonin receptor has been shown to play an important role in calcium homeostasis, particularly in states of calcium stress (e.g., vitamin D toxicity). Calcitonin from salmon sources is most commonly administered subcutaneously or intramuscularly (for larger volumes) in a starting dose of 4 units/kg every 12 hours. The side effects from intravenously administered calcitonin (facial flushing, nausea, and vomiting) limit patient acceptability. Allergic reactions, although rare, do occur; therefore a test dose (intradermal injection of 0.1 mL of a 10-units/mL solution) is recommended prior to starting therapy. If marked erythema and/or wheal formation does not occur within 15 minutes after administration, therapy can begin. Salmon calcitonin therapy is associated with tachyphylaxis caused by antibody formation to foreign proteins or molecules resembling the calcitonin polypeptide. Tachyphylaxis has been primarily documented in patients receiving therapy for more than 4 months and thus might not be clinically significant in the acute care setting. The addition of corticosteroid therapy or conversion to human calcitonin increases effectiveness.

Finally, intravenous phosphate was used historically to rapidly reduce ionized calcium concentrations through the formation of insoluble calcium-phosphate salts. However, intravenous phosphate is extremely hazardous because extraskeletal (e.g., intraluminal and intrarenal) precipitation of calcium-phosphate can result in metastatic calcification, hypotension, acute renal failure, or death and thus it currently does not have a role in the management of acute hypercalcemia.
Bisphosphonates block bone resorption very efficiently, render the hydroxyapatite crystal of bone mineral resistant to hydrolysis by phosphatases, and also inhibit osteoclast precursors from attaching to the mineralized matrix, thus blocking their transformation into mature functioning osteoclasts.\textsuperscript{15,26} The antiresorptive properties of this class of agents can provide long-term control of serum calcium and are the first-line therapy for cancer-associated hypercalcemia.

Pamidronate is very effective in controlling hypercalcemia associated with malignancy and slightly more effective than etidronate.\textsuperscript{7} The usual dose of pamidronate is 30 to 90 mg as an IV infusion given over 2 to 24 hours. Pamidronate also has the advantage of single-day therapy.\textsuperscript{9} Etidronate, when administered in doses of 7.5 mg/kg per day by slow intravenous infusion over at least 2 hours for 3 days, is effective in the therapy of hypercalcemia of malignancy.\textsuperscript{2} Zoledronate and ibandronate are the newest high-potency bisphosphonates with demonstrated effectiveness in the treatment of hypercalcemia of malignancy. Complete response has been reported in 88.4% to 86.7% of zoledronate-versus 69.7% of pamidronate-treated patients.\textsuperscript{27,28} Zoledronate intravenous doses of 4 to 8 mg given over 5 minutes have resulted in normalization of serum calcium concentrations.\textsuperscript{28} Intravenous infusions of 0.02 or 0.04 mg/kg diluted in 5% dextrose (given over 20–50 minutes) have also been effective.\textsuperscript{29} A similar hypocalcemic response has been noted with ibandronate in comparison with pamidronate (76.5% vs 75.8%); however, the time period to a relapse of hypercalcemia was longer with ibandronate (14 days vs 4 days), suggesting a therapeutic advantage for ibandronate.\textsuperscript{30} In contrast to other bisphosphonates, ibandronate can be administered by bolus injection. Single doses of 4 to 6 mg when administered every 3 to 4 weeks have been effective in managing hypercalcemia of malignancy.\textsuperscript{31} The onset of serum calcium concentration decline is slower with bisphosphonate therapy (concentrations begin to decline in 2 days and reach a nadir in 7 days); thus calcitonin therapy can be necessary if rapid serum level reduction is required.\textsuperscript{9,31} Duration of normocalcemia varies, but usually does not exceed 2 to 3 weeks. It appears to be dependent on the severity and treatment response of the underlying malignancy.\textsuperscript{2} The duration of response has been suggested to be longer with zoledronate (4–5 weeks), although the data is sparse.\textsuperscript{29} Fever is a common side effect of intravenous bisphosphonate therapy. Although oral bisphosphonates are useful for the treatment of bone turnover in Paget disease, there are insufficient data to suggest their use for the initial treatment of hypercalcemia. The use of oral bisphosphonates for maintenance therapy in patients predisposed to hypercalcemia (malignancy) has been successful in some cases.\textsuperscript{32} The safety of continuous bisphosphonate therapy in patients with moderate to severe renal insufficiency is currently unknown. Renal function monitoring (serum creatinine) is advised with the use of bisphosphonates, as cases of acute tubular necrosis have been reported.\textsuperscript{33,34} Although there are no published guidelines for frequency of serum creatinine monitoring, it is advisable to evaluate serum creatinine within a week after the infusion and just prior to the next scheduled dose.

**CLINICAL CONTROVERSY**

Bisphosphonates are renally eliminated and prescribing information advises that they be used with caution in patients with a GFR less than 30 mL/min (<0.5 mL/s); however, many clinicians use these agents for first-line treatment of cancer-related hypercalcemia.

Gallium nitrate is indicated for the treatment of symptomatic hypercalcemia of malignancy not responsive to hydration therapy.\textsuperscript{35} However, because of its adverse side-effect profile, it is generally reserved for those who fail to respond to less toxic agents. Gallium nitrate inhibits bone resorption, and may be superior to calcitonin in inducing normocalcemia. It can provide a longer duration of normocalcemia as compared with etidronate. The initial dose is usually a continuous IV infusion of 200 mg/m\textsuperscript{2} per day for 5 consecutive days. Gallium nitrate can be more effective in achieving normocalcemia in patients with epidermoid (squamous) cancers.\textsuperscript{36} Because gallium nitrate is nephrotoxic, the initial dose should be conservative and the patient’s renal function closely monitored if it is coadministered with other nephrotoxic drugs, including some chemotherapeutic agents, nonsteroidal anti-inflammatory drugs (NSAIDs), and antibiotics (e.g., gentamicin). Other common adverse effects include hypophosphatemia, nausea, vomiting, diarrhea, hypocalcemia, and metallic taste.

Mithramycin (plicamycin) is a potent cytotoxic antibiotic that inhibits osteoclast-mediated bone resorption and thereby reduces hypercalcemia. Mithramycin can be administered at a dose of 25 mcg/kg via intravenous infusion over 4 to 6 hours in saline or 5% dextrose solutions. This therapy can be repeated daily for 3 to 4 days or on alternating days for 3 to 8 doses.\textsuperscript{37} Serum calcium levels begin to fall within 12 hours of a mithramycin dose, with the peak effect generally occurring over 48 to 96 hours.\textsuperscript{38} Single doses are usually well tolerated.\textsuperscript{37} Common dose-related adverse effects of mithramycin include nausea, vomiting, stomatitis, thrombocytopenia, inhibition of platelet function, and renal and hepatotoxicity can be avoided by limiting the number of doses administered to less than four.\textsuperscript{2} Mithramycin is usually limited to short-term therapy (typically one to two doses) in patients who have not responded to alternative therapies. Complete blood count, liver function, and renal function should be monitored within 1 to 2 days after administration. Mithramycin should be avoided in patients with thrombocytopenia and liver and renal insufficiency (creatinine clearance <30 mL/min <0.5 mL/s)).\textsuperscript{39}

Denosumab is a monoclonal antibody that inhibits the receptor activator of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) ligand (RANKL), a principal mediator of osteoclast survival. Denosumab is in phase III clinical trials for the treatment of osteoporosis. Recently, denosumab has been investigated in patients with malignancies and bone metastases (without hypercalcemia) who were either bisphosphonate naïve or who had previous exposure to bisphosphonates. Patients were randomized to receive an IV bisphosphonate every 4 weeks (91% received zoledronic acid) or a fixed dose of denosumab every 4 weeks (30, 120, 180 mg) or every 12 weeks (60, 180 mg) to investigate the effect on the primary outcome measure of urinary-N-telopeptide, a marker for bone turnover. Patients who were bisphosphonate naïve had similar decline in markers of bone turnover. In patients with previous exposure to bisphosphonates, treatment with denosumab produced significantly greater reductions in bone turnover compared with an IV bisphosphonate. These preliminary results indicate that denosumab reduces bone turn over and may be efficacious in preventing or treating hypercalcemia of malignancy.\textsuperscript{38}

Prednisone or an equivalent agent in the corticosteroid class is usually effective in the treatment of hypercalcemia resulting from multiple myeloma, leukemia, lymphoma, sarcoidosis, and hypervitaminoses A and D.\textsuperscript{2,26,37} These agents are effective because they reduce gastrointestinal calcium absorption and decrease renal tubular calcium reabsorption.\textsuperscript{37} Corticosteroids may also prevent tachyphylaxis to salmon calcitonin.\textsuperscript{21} Daily doses of 40 to 60 mg of prednisone or the equivalent are effective at reducing serum calcium within 3 to 5 days followed by a reduction in urinary calcium excretion within 7 to 10 days. The disadvantages of corticosteroid therapy are its relatively slow onset of action and the
Potential for diabetes mellitus, osteoporosis, and increased susceptibility to infection.

Asymptomatic patients with mild hypercalcemia may be carefully observed, especially if treatment for the underlying condition (malignancy) is initiated. The calcimimetic agent cinacalcet HCl was recently approved for its calcium-lowering effect in the management of parathyroid carcinoma.  It binds to the calcium-sensing receptor, and increases the sensitivity for receptor activation by extracellular calcium. This results in reduced PTH and calcium concentrations.  The lack of significant efficacy of the synthetic intranasal formulation of calcitonin has been used in doses of 200 to 400 international units daily; unfortunately, this has resulted in only mild decreases in serum calcium. Potassium citrate preferred over sodium citrate as it decreases urinary calcium, inhibits calcium oxalate precipitation, and increases urinary citrate more.

**TREATMENT OF NEPHROLITHIASIS ASSOCIATED WITH CHRONIC HYPERCALCENIA AND HYPERCALCIURIA**

**HYPOCALCEMIA**

Hypocalcemia is the result of alterations in the effect of PTH and vitamin D on the bone, gut, and kidney (see Fig. 59-1). The primary causes of hypocalcemia are postoperative hypoparathyroidism and vitamin D deficiency. Other causes include magnesium deficiency, thyroid surgery, medications, hyperalbinemia, blood transfusions, peripheral blood progenitor cell harvesting, tumor lysis syndrome, and mutations in the calcium-sensing receptor. 46–49 PTH concentrations are elevated in conditions of hypocalcemia, with the exception of hypoparathyroidism and hypomagnesemia.

**VITAMIN D DEFICIENCY**

Vitamin D and its metabolites play an important role in the maintenance of extracellular calcium concentrations and in normal
skeletal structure and mineralization. Vitamin D is necessary for the optimal absorption of calcium and phosphorus. On a worldwide basis, the most common cause of chronic hypocalcemia is nutritional vitamin D deficiency. In malnourished populations, manifestations include rickets and osteomalacia. Nutritional vitamin D deficiency is uncommon in Western societies because of the fortification of milk with ergocalciferol. The most common cause of vitamin D deficiency in Western societies is gastrointestinal disease. Gastric surgery, chronic pancreatitis, small-bowel disease, intestinal resection, and bypass surgery are associated with decreased concentrations of vitamin D and its metabolites. Vitamin D replacement therapy might need to be administered by the intravenous route if poor oral bioavailability is noted. Decreased production of 1,25-dihydroxyvitamin D can occur as a result of a hereditary defect resulting in vitamin D–dependent rickets. Recently, polymorphisms of the vitamin D receptor have been identified, and these genetic variations can contribute to increased risk of rickets associated with vitamin D and calcium deficient diets, especially in certain African and East Asian populations. It also can occur secondary to chronic kidney disease if there is insufficient production of the 1-α-hydroxylase enzyme for the production of the most active metabolite, 1,25-dihydroxy vitamin D. Treatment of hypocalcemia associated with CKD is reviewed in Chapter 53.

Hypomagnesemia

Hypomagnesemia of any cause can be associated with severe symptomatic hypocalcemia that is unresponsive to calcium replacement therapy (see Chapter 60). Reduced serum magnesium concentrations can impair PTH secretion and induce resistance of target organs to the actions of PTH. Normalization of serum calcium concentrations in these patients is thus dependent on appropriate replacement of magnesium.

Tissue Consumption of Calcium

Decreased total serum calcium concentrations are seen in up to 10% of patients with acute pancreatitis, principally due to low serum albumin concentrations. These patients typically have more severe attacks, a poorer prognosis, and increased mortality rates. The mechanisms responsible for the development of true hypocalcemia in pancreatitis have not been completely elucidated but may include binding of calcium to liberated fatty acids or possibly transcellular shifts induced by gram-negative endotoxin translocated from the gastrointestinal tract. The etiology of sepsis-associated hypocalcemia may be the result of inflammatory mediators affecting calcium homeostasis. Finally, rhabdomyolysis and tumor lysis syndrome can result in acute elevations of serum phosphorus that can bind ionized calcium.

Hungry Bone Syndrome

An acute, symptomatic rapid fall in total serum calcium concentration (to values <7 mg/dL [<1.75 mmol/L]) is common in patients who have recently had a parathyroidectomy or thyroidectomy. Hypocalcemia in these postsurgical patients is generally transient in nature. The “hungry bone syndrome” is a condition of profound hypocalcemia whereby the bone avidly incorporates calcium and phosphorus from the blood in an attempt to recalcify bone. Serum calcium concentrations should be monitored every 6 hours during the 24 to 48 hours following such surgeries, and pharmacologic doses of calcium can be necessary to prevent or minimize the drop in serum calcium. Additionally, mild to moderate hypocalcemia can be a long-term consequence of parathyroidectomy in hemodialysis patients.

Drug-Induced Hypocalcemia

Drug-induced hypocalcemia has been reported in patients receiving furosemide, calcitonin, bisphosphonates, gallium nitrate, mithramycin, cinacalcet, fluoride, ketoconazole, and pentamidine. Oral phosphorus therapy, commonly used to treat patients with malabsorption syndromes caused by gastrointestinal diseases, can also result in hypocalcemia. The anticonvulsants phenobarbital and phenytoin cause hypocalcemia by increasing catabolism of vitamin D and thereby impairing calcium release from bone and reducing intestinal calcium absorption. Drugs that cause hypomagnesemia (aminoglycosides, amphotericin B, cyclosporine, diuretics, foscarinet, and cisplatin) are also associated with an increased risk of hypocalcemia. Chelating agents in blood (citrate) and in radiographic contrast media (ethylenediamine tetraacetate) can also cause transient hypocalcemia.

Concentrated citrate is increasingly being used in hemodialysis catheter locks and to anticoagulate the dialysis circuit during continuous renal replacement therapy. Symptomatic hypocalcemia (ionized calcium <2.4 mg/dL [<0.60 mmol/L]) has been reported in patients exposed to citrate solutions, which appears to be related to the concentration of the citrate solution. Injection of citrate solutions greater than the volume of the dead space of the catheter lumen or accidental injection of citrate catheter lock solutions that are not intended for systemic administration have been associated with serious cardiovascular problems such as hypotension or cardiac arrest.

Hypoparathyroidism

Hypoparathyroidism can be caused by autoimmune disease, congenital defects, or iatrogenically by inadvertent removal during thyroidectomy or from damage with radiation therapy. Chronic hypoparathyroidism produces an insidious development of hypocalcemia and thus most patients remain asymptomatic. The chronic hypocalcemia may ultimately present as visual impairment secondary to cataracts.

CLINICAL PRESENTATION

The clinical manifestations of hypocalcemia are quite variable. The more acute the drop in ionized calcium concentration, the more likely the patient will develop symptoms. Increases in plasma pH enhances the binding of calcium to albumin thus alkalosis can result in rapid decreases in ionized calcium. Concomitant hypomagnesemia, hypokalemia, hyponatremia, and additive side effects from prescribed medications also increase the likelihood of symptomatic presentation.

Hypocalcemia can manifest as neuromuscular, CNS, dermatologic, and cardiac sequelae. Acute hypocalcemia is more likely to manifest as neuromuscular (paresthesia, muscle cramps, tetany, and laryngeal spasm) and cardiovascular symptoms, whereas chronic hypocalcemia often presents as CNS (e.g., depression, anxiety, memory loss, confusion, hallucinations, and tonic-clonic seizures) and dermatologic symptoms (hair loss, grooved and brittle nails, and eczema). The hallmark sign of acute hypocalcemia is tetany caused by enhanced peripheral neuromuscular irritability. Tetany manifests as paresthesia around the mouth and in the extremities, muscle spasms and cramps, carpopedal (hands and feet) spasms, and rarely as laryngospasm and bronchospasm. Chvostek’s sign is elicited by tapping the facial nerve anterior to the ear and eliciting twitching of facial muscles. Chvostek’s sign is elicited by inflating a blood pressure cuff above systolic blood pressure for 3 minutes and observing whether a carpal spasm is induced.
The cardiovascular manifestations of hypocalcemia result in electrocardiographic changes characterized by a prolonged QT interval and symptoms of decreased myocardial contractility often associated with congestive heart failure. Both acute and chronic hypocalcemia can result in a reversible syndrome characterized by acute myocardial failure or refractory congestive heart failure. Other cardiovascular manifestations include arrhythmias, bradyarrhythmias, and hypotension that are unresponsive to fluid and pressor administration.

## Clinical Presentation of Hypocalcemia

### General
- Hypocalcemia is caused in part by disorders of vitamin D or PTH. Acute causes of hypocalcemia result in rapid decreases in serum ionized calcium and can be associated with sepsis, alkalosis, or drugs. Parathyroidectomy or thyroidecтомy are also associated with a rapid reduction in serum calcium. Vitamin D deficiency associated with malnutrition should not be overlooked as an etiology of chronic hypocalcemia.

### Symptoms
- The symptoms of hypocalcemia, usually associated with an acute decrease in serum calcium, include tetany, paresthesia, muscle cramps, and laryngeal spasms. Chronic hypocalcemia is usually associated with the symptoms of depression, anxiety, memory loss, and confusion.

### Signs
- Neurologic: The hallmark of acute hypocalcemia is tetany, which is characterized by neuromuscular irritability including seizure potential. Extrapyramidal disorders, mainly parkinsonism but also dystonia, hemiballismus, choreoathetosis, and oculogryric crises occur in 5% to 10% of patients with idiopathic hypoparathyroidism. Chvostek’s and/or Trouseau’s signs can be elicited during physical examination.

- Dermatologic: The skin can be dry, puffy, and coarse. Other dermatologic manifestations can include hyperpigmentation, dermatitis, eczema, and psoriasis. Hair and skin signs including coarse, brittle, and sparse hair with patchy alopecia and brittle nails can also appear.

- Ophthalmologic: Cataract development has been reported to occur with hypocalcemia.

- Dental manifestations: These are usually associated with the presence of chronic hypocalcemia in early development. Signs include dental hypoplasia, failure of tooth eruption, defective enamel and root formation, and abraded carious teeth.

- Cardiovascular: Hypotension, decreased myocardial performance, and congestive heart failure have been reported. A prolonged QT interval, arrhythmias, and bradycardia can also occur but are more common with acute or very severe hypocalcemia.

- Gastrointestinal: Steatorrhea can be associated with chronic hypocalcemia.

- Musculoskeletal: Although patients with chronic hypocalcemia disorders have skeletal abnormalities, such findings do not appear to be direct consequences of hypocalcemia. Some patients with hypocalcemia have myopathy.

- Endocrine: Hypocalcemia alone can impair insulin release. In addition, idiopathic hypoparathyroidism can be associated with polyglandular autoimmune syndromes.

## Laboratory Tests
- Serum calcium levels of less than 8.5 mg/dL (<2.13 mmol/L) are considered to represent hypocalcemia if ionized calcium values are also less than 4.4 mg/dL (<1.1 mmol/L).

## Treatment
### Hypocalcemia

#### Desired Outcome
- The goals of therapy for patients with normal renal function are the resolution of signs and symptoms of hypocalcemia, restoration of normocalcemia, management of associated electrolyte abnormalities, and treatment of the underlying cause of hypocalcemia. The goals for patients with chronic kidney disease are different and are discussed in detail in Chapter 53. Asymptomatic hypocalcemia associated with hypoalbuminemia requires no treatment because ionized (physiologically active) plasma calcium concentrations are normal. Treatment of hypocalcemia is dependent on identification of the pathogenesis of the underlying disorder, acuteness of onset, and presence and severity of symptoms. Acute symptomatic hypocalcemia requires parenteral administration of soluble calcium salts (Fig 59–3).

#### Pharmacologic Therapy

The initial therapeutic intervention for patients with acute symptomatic hypocalcemia is to administer 100 to 300 mg of elemental calcium intravenously over 5 to 10 minutes. This can be accomplished by the administration of 1 g of calcium chloride (27% elemental calcium) or 2 to 3 g of calcium gluconate (9% elemental calcium). Calcium gluconate is generally preferred over calcium chloride for peripheral venous administration because calcium gluconate is less irritating to veins. The use of calcium gluconate provides a less predictable and slightly smaller increase in plasma ionic calcium compared with calcium chloride. Calcium should not be infused at a rate greater than 60 mg of elemental calcium per minute because severe cardiac dysfunction, including ventricular fibrillation, can result. Intravenous calcium administration should be used with caution in patients receiving digitalis glycosides because of the possibility of bradycardia or atrioventricular (A-V) block. The bolus dose of calcium is only effective for 1 to 2 hours and should be followed by a continuous infusion of elemental calcium at a rate of 0.5 to 2 mg/kg per hour. The calcium concentrations should be monitored every 4 to 6 hours during the intravenous infusions. The ionized calcium concentration usually normalizes within 4 hours, and the maintenance infusion rate of elemental calcium can then be decreased to 0.3 to 0.5 mg/kg per hour to maintain the desired calcium concentration. Calcium should not be added to bicarbonate- or phosphate-containing solutions because of the possibility of precipitation.

Once acute hypocalcemia is corrected by parenteral administration, further treatment modalities should be individualized according to the cause of hypocalcemia. If hypomagnesemia is present, magnesium supplementation is indicated (see Chapter 60). Hypocalcemia secondary to hungry bone syndrome following parathyroidectomy has been attenuated by pretreatment with bisphosphonates. Asymptomatic and chronic hypocalcemia associated with hypoparathyroidism and vitamin D–deficient states can be managed by oral calcium and vitamin D supplementation (see Chapter 53). Therapy is begun with 1 to 3 g/day of elemental calcium. Average maintenance doses range...
from 2 to 8 g of elemental calcium per day in divided doses. If serum calcium does not normalize, a vitamin D preparation may need to be added.

Treatment of hypocalcemia associated with vitamin D–deficient states should be individualized. In patients with malabsorption, vitamin D requirements vary markedly, and large doses can be required. In contrast, vitamin D deficiency associated with anticonvulsant medication can be corrected with smaller doses of vitamin D. Oral doses of 1,25-dihydroxy vitamin D usually range from 0.5 to 3 mcg daily. The usual initial oral dose of ergocalciferol is 50,000 international units daily. Vitamin D doses are usually adjusted approximately every 4 weeks. Vitamin D deficiency is highly prevalent especially in areas of low sun exposure and limited dietary sources of vitamin D. New data suggest that current dietary recommendations are not sufficient to maintain 25-hydroxy vitamin D concentrations at or above 32 mcg/L (90 mmol/L). The treatment of vitamin D deficiency associated with CKD generally requires the administration of 1,25-dihydroxy vitamin D, or another synthetic vitamin D analog such as paricalcitol or doxercalciferol. Patients who have reduced 25-hydroxylase activity (e.g., hepatic disease) can also require treatment with calcitriol (1,25-dihydroxy vitamin D). The treatment of hypocalcemia associated with CKD generally requires the administration of 1,25-dihydroxy vitamin D, or another synthetic vitamin D analog such as paricalcitol or doxercalciferol. The newer vitamin D analogs (paricalcitol and doxercalciferol) were developed to preferentially suppress PTH secretion with less effect on serum calcium concentration and thus their efficacy for the management of hypocalcemia may be minimal. In selected cases, increasing calcium ingestion can be required if vitamin D replacement alone is ineffective in returning calcium concentrations to normal.

Adverse effects of oral calcium and vitamin D supplementation include hypercalcemia and hypercalciuria, especially in the hypoparathyroid patient, in whom the renal calcium-sparing effect of PTH is absent. Hypercalciuria can increase the risk of calcium stone formation and nephrolithiasis in susceptible patients. One maneuver to help prevent calcium stones is to maintain the urine calcium excretion below 300 mg per day. Intermittently monitoring 24-hour urine collections for total calcium excretion can help to minimize the occurrence of hypercalciuria. The addition of thiazide diuretics for patients at risk for stone formation can result in an increase in tubular calcium reabsorption and reduction of vitamin D requirements.

### DISORDERS OF PHOSPHORUS HOMEOSTASIS

Inorganic phosphorus in the form of phosphate is an essential element in phospholipid cell membranes, nucleic acids, and phosphoproteins, which are required for mitochondrial function. Phosphorus regulates the intermediary metabolism of carbohydrates, fats, and proteins. Phosphorus also regulates enzymatic reactions including glycolysis, ammoniagenesis, and the 1-hydroxylation of 25-hydroxy vitamin D. In addition, phosphorus is required for the generation of 2,3-diphosphoglycerate (2,3-DPG) in red blood cells, which is required for normal oxygen-hemoglobin dissociation and delivery of oxygen to the tissues. Phosphorus is the source of the high-energy bonds of adenosine triphosphate (ATP), thus fueling a wide variety of physiologic processes, including muscle contractility, electrolyte transport, neurologic function, and other important biochemical reactions. Considering its diverse biologic importance, it is not difficult to appreciate the clinical implications of disorders of phosphorus homeostasis.

Phosphate, the major intracellular anion, is present in living organisms mainly as organic phosphate esters such as 2,3-DPG, adenosine, guanosine triphosphate, and fructose 1,6-diphosphate. Only a small fraction of intracellular phosphate exists as inorganic phosphate; however, this fraction is critical because it is the source from which ATP is resynthesized. The majority of inorganic phosphate is located in the extracellular space where it is the prime determinant of intracellular phosphate; thus, small increments in
the organic phosphate levels can profoundly alter both the extracellular and intracellular phosphate levels. Metabolic disturbances (acidosis, alkalosis, and ketoacidosis), hydrogen ion shifts, and hormones (PTH, calcitonin, cortisol, and vitamin D) all can cause transcellular shifts in phosphate concentrations. Because of these phenomena, the serum phosphate level does not accurately reflect total body stores.

The typical Western diet provides a daily intake of 800 to 1,600 mg of phosphorus. Approximately 60% to 80% of this is absorbed in the gastrointestinal tract by passive and active transport (vitamin D mediated). PTH, 1,25-dihydroxy vitamin D₃, and low-phosphate diets mediate increased absorption. Decreased absorption occurs under conditions of increased dietary intake of phosphorus and magnesium, glucocorticoid therapy, and hypothyroidism. The normal serum phosphorus concentration in adults is 2.5 to 4.5 mg/dL (0.81–1.45 mmol/L) and for children younger than 12 years old it is 4 to 5.6 mg/dL (1.29–1.81 mmol/L). Influx via the gastrointestinal tract and bone and tubular reabsorption by the kidney are the most important regulators of steady-state serum phosphate concentrations. Renal excretion of phosphorus is a two-step process: glomerular filtration and proximal tubular reabsorption by passive transport coupled to sodium. Under normal conditions, 85% to 90% of filtered phosphate is reabsorbed, the majority in the early proximal tubule. Renal tubular reabsorption of phosphate is inhibited by PTH and 1,25-dihydroxy vitamin D₃. There are increasing data in the literature that indicate fibroblast growth factor 23 (FGF23) is a key regulator of phosphate homeostasis. FGF23 acts principally to decrease tubular reabsorption of phosphate and inhibit 1α-hydroxylase, thereby reducing the concentration of active vitamin D. FGF23-mediated receptor activation requires klotho, a transmembrane protein. The tissue specificity for FGF23 effects appears to be defined by klotho-FGF23 coexpression. Conversely, phosphate reabsorption in the renal tubule is increased by growth hormone, insulin and insulin-like growth factor 1. Internal phosphorus balance (transcellular phosphate distribution) is also of importance in the maintenance of normal serum phosphate. The serum phosphate level can vary by as much as 2 mg/dL (0.65 mmol/L) throughout the day, primarily as the result of changes in carbohydrate intake, insulin secretion, and diurnal variation.

**HYPERPHOSPHATEMIA**

Hyperphosphatemia typically results from either renal failure or endogenous intracellular phosphate release. Hyperphosphatemia occurs frequently in patients with acute renal failure and is a nearly universal finding in those with advanced stages of CKD (e.g., stages 4 and 5). Tumor lysis syndrome is a complication of chemotherapy associated with massive lysis of cells and release of intracellular contents. The incidence of tumor lysis syndrome has been reported to be as high as 40% in patients treated for non-Hodgkin lymphoma. Other causes of hyperphosphatemia include hemolysis and rhabdomyolysis.

**Pathophysiology**

The most common cause of hyperphosphatemia is a failure of renal tubular reabsorption to maintain serum phosphate when GFR is markedly impaired (e.g., GFR <25 mL/min [<0.42 mL/s]). Retention of phosphate decreases vitamin D synthesis and induces hypocalcemia, which leads to an increase in PTH, a finding that can be seen in those with stage 2 to 3 CKD. This physiologic response inhibits further tubular reabsorption of phosphorus as the kidney attempts to correct hyperphosphatemia and normalize serum calcium concentrations. Patients with excessive exogenous phosphate administration or who experience massive tissue breakdown or cell lysis in the setting of acute renal failure can rapidly develop moderate to severe hyper-phosphatemia (serum phosphate >6.5 mg/dL [>2.10 mmol/L]). Severe hyperphosphatemia (serum phosphate >7.0 mg/dL [>2.26 mmol/L]) is commonly encountered in patients with CKD, especially those with GFRs less than 15 mL/min per 1.73 m² (0.14 mL/min/m²) (see Chapter 53).

Hyperphosphatemia caused by an increase in renal tubular reabsorption associated with hypoparathyroidism and associated decreases in PTH is usually less severe than that observed in patients with severe renal failure or excessive exogenous or endogenous introduction of phosphate into the ECF. Acromegaly (mediated by growth hormone) and thyrotoxicosis (mediated by catecholamines) can also cause hyperphosphatemia by increasing tubular phosphate reabsorption.

**Exogenous Phosphate Loads**

Iatrogenic causes of hyperphosphatemia have been widely reported, and clinicians should be aware of the phosphorus content of intravenous, oral, and rectally administered products. Large doses of phosphate administered intravenously to treat hypercalcemia can ultimately result in severe life-threatening hyperphosphatemia. Although less-well recognized, oral and rectal administration of phosphate-containing solutions such as sodium phosphate (Fleet Phospho-Soda) can also result in severe and life-threatening hyperphosphatemia, especially in patients with moderate and severe renal insufficiency. The risk of mortality is dependent on the amount of phosphorus absorbed from the administered product, however, fatalities have occurred at lower phosphate concentrations. Acute phosphate nephropathy and renal failure have also been reported with the use of oral sodium phosphate bowel preparations. Recently the FDA issued a safety warning regarding the use of these products in patients at risk (the elderly, those with CKD) or on medications known to effect renal hemodynamics (e.g., diuretics, NSAIDs or renin-angiotensin-aldosterone system inhibitors). Intravenous or oral vitamin D therapy can increase absorption of phosphorus in the gastrointestinal tract by up to 50%. High-dose etidronate (10–20 mg/kg/d) therapy has been associated with increased serum phosphate concentrations apparently mediated by drug-related increase in tubular phosphate reabsorption. Acute phosphate poisoning as a result of ingestion of laundry detergents is a rare and often unrecognized cause of elevated phosphate concentrations.

**Rapid Tissue Catabolism**

Any disorder that results in necrosis of skeletal muscle (i.e., rhabdomyolysis) can generate the release of large amounts of intracellular phosphate into the systemic circulation. This condition is frequently associated with acute kidney injury (see Chapter 51) and thus severe hyperphosphatemia can develop because of increased endogenous phosphate release coupled with the impaired proximal tubule reabsorption such that phosphaturic hormones (e.g., PTH, FGF23) become ineffective. Bowel infarction, malignant hyperthermia, and severe hemolysis are also conditions that can increase endogenous release of phosphate.

Moderate hyperphosphatemia is also commonly observed in patients undergoing treatment for acute leukemia and lymphomas. Chemotherapeutic treatment of acute lymphoblastic leukemia can result in the release of large amounts of phosphate into the systemic circulation secondary to lysis of lymphoblasts. Initiation of chemotherapy for Burkitt lymphoma results in tumor lysis syndrome, a rapid lysis of malignant cells that results in hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia.

**Acid–Base Disorders**

Lactic acidosis and diabetic ketoacidosis can trigger the transcellular shift of endogenous intracellular phosphate into the extracellular space and thereby dramatically increases serum...
phosphorous concentrations. In one study, hyperphosphatemia was present in more than 90% of patients with diabetic ketoacidosis prior to the initiation of treatment. After the institution of treatment, serum phosphate levels should be checked hourly as they can decrease rapidly, and patients can ultimately develop hypophosphatemia.

**Clinical Presentation**

The severe acute onset of hyperphosphatemia can result in calcium and phosphate complexation and lead to the precipitation of calcium phosphate into soft tissues, intrarenal calcification, nephrolithiasis, or obstructive uropathy. Other symptoms associated with moderate to severe hyperphosphatemia include nausea, vomiting, diarrhea, lethargy, and seizures. The major effects of long-term hyperphosphatemia are related to the development of hypocalcemia (caused by phosphate inhibition of renal 1-α-hydroxylase) and its related consequences, as well as vascular and organ damage resulting from the deposition of calcium-phosphate crystals. Extravascular calcification can result in band keratopathy, “red eye,” pruritus, and periarticular calcification, especially in CKD patients. In addition, soft-tissue calcifications in the conjunctiva, skin, heart, cornea, lung, gastric mucosa, and kidney have been observed, primarily in CKD patients with chronic disordered mineral metabolism. Hyperphosphatemia associated with CKD can result in renal osteodystrophy because of overproduction of PTH. This condition is discussed in detail in Chapter 53.

**TREATMENT**

**Hyperphosphatemia**

**DESIRED OUTCOME**

Management of patients with acutely elevated serum phosphate should be directed at avoiding gastrointestinal and neurologic symptoms and preventing deposition in the urinary tract to avoid the development of acute renal failure. The treatment of hyperphosphatemia is focused on returning serum phosphate concentrations to the normal or near normal (for those with CKD) range, with the hope that one can minimize the long-term cardiovascular consequences of calcium-phosphate crystal deposition in the vasculature. Calcium-phosphate crystals are likely to form in vivo when the product of the serum calcium and phosphate concentrations exceeds 50 to 60 mg²/dL² (4.0–4.8 mmol²/L²). The National Kidney Foundation’s Dialysis Outcomes Quality Initiative guidelines for bone metabolism and disease defines the goal calcium-phosphorus product as less than 55 mg²/dL² (4.4 mmol²/L²). Furthermore, serum phosphate concentrations greater than 6.5 mg/dL (2.10 mmol/L) have been independently associated with increased morbidity and mortality. Serum phosphate concentrations should be maintained in the 2.7 to 4.6 mg/dL (0.87–1.49 mmol/L) range for those with stages 3 and 4 CKD, whereas for patients in stage 5 CKD the goal is to maintain values between 3.5 and 5.5 mg/dL (1.13–1.78 mmol/L).

**PHARMACOLOGIC THERAPY**

Severe symptomatic hyperphosphatemia manifesting as hypocalcemia and tetany should be treated by the intravenous administration of calcium salts. Although this can seem counterintuitive in a patient with a phosphate of 16 mg/dL (5.17 mmol/L) and a calcium of 7 mg/dL (1.75 mmol/L) (the calcium-phosphorus product is 112 mg²/dL² [9.0 mmol²/L²]), correction of severe hypocalemia is of primary importance because of the critical nature of this disorder. If calcium concentrations are not critically low, the initial management strategy should include limitation of all exogenous sources of phosphate and efforts to block further absorption should be initiated. Dialysis can be initiated if the patient remains symptomatic despite these interventions.

In general, the most effective way to treat nonemergent hyperphosphatemia is to decrease phosphate absorption from the GI tract by the use of phosphate-binding agents. Antacids containing divalent and trivalent cations (calcium, lanthanum, magnesium, and aluminum), or sevelamer are the agents most frequently used in the prevention and treatment of hyperphosphatemia (see Table 53–8). Long-term treatment with aluminum hydroxide and aluminum carbonate should be discouraged because the use of these agents has been associated with anemia, CNS disorders, and bone disease. Short-term therapy with these agents is effective and safe. Aluminum and calcium are available in oral suspension formulations, which can aid administration in acutely ill patients with G-tubes. The most frequent adverse effect from phosphate-binding agents (especially calcium) is constipation (see Table 53–8). Calcium salts are the preferred phosphate-binding agents except when there is concomitant hypercalcemia. Therapy with the polymer agent (sevelamer) or lanthanum carbonate might avoid the detrimental effects associated with aluminum, magnesium, or calcium therapy.

**CLINICAL CONTROVERSY**

Emerging data suggest that noncalcium, nonaluminum phosphate binders can slow progression of cardiac calcification in chronic hemodialysis patients; however, there are no data to suggest that there are any benefits to using sevelamer for the management of those who develop acute hyperphosphatemia. Thus, a more cost-effective approach to phosphate binding in acute situations would be use of calcium- or aluminum-based binders.

**HYPOPHOSPHATEMIA**

Mild to moderate hypophosphatemia is typically found in patients with serum phosphate concentrations of 1 to 2 mg/dL (0.32–0.65 mmol/L), whereas severe hypophosphatemia that is...
frequently symptomatic is correlated with a phosphorus concentration of less than 1 mg/dL (0.32 mmol/L). Hypophosphatemia has been observed in approximately 1% to 3% of the laboratory screening panels of patients who have been admitted to a hospital. The incidence in hospitalized critically ill patients is 18% to 28%. Unlike its severe form, mild or moderate hypophosphatemia seldom causes recognizable signs and symptoms.

**PATHOPHYSIOLOGY**

Hypophosphatemia can be the result of decreased gastrointestinal absorption, reduced tubular reabsorption, or extracellular to intracellular redistribution. Although mild to moderate hypophosphatemia is common and can occur in inpatients and outpatients, severe hypophosphatemia is primarily encountered in the acute care setting and can be associated with life-threatening symptoms, including seizures, coma, and rhabdomyolysis (Table 59-4).

Phosphate-binding substances such as sucralfate, calcium carbonate, sevelamer, lanthanum carbonate, and aluminum- or magnesium-containing antacids have the potential to bind large amounts of phosphorus in the gut, thereby preventing absorption. If phosphate-binding agents are ingested on a chronic basis in conjunction with a dietary phosphorus deficiency, hypophosphatemia can result. Patients who are receiving long-term phosphate-binding agents, those with peptic ulcer disease or CKD, and those who may be predisposed to moderate hypophosphatemia (alcoholics) are at highest risk for the development of severe hypophosphatemia. Hyperparathyroidism can cause hypophosphatemia as a result of decreased gastrointestinal absorption of dietary phosphorus.

Reduced tubular reabsorption of phosphate can occur in hyperparathyroid (primary and secondary) patients with normal renal function and those with vitamin D deficiency or elevated FGF23 concentrations. Elevated PTH levels lead to an increase in serum calcium concentrations and decreased serum phosphate concentrations. Serum phosphorus is decreased as the result of a reduction in renal tubular reabsorption. Recovery from extensive third degree burns is associated with development of an anabolic state as stress levels decrease and nutritional therapies take effect as well as a marked diuretic phase associated with an impressive renal loss of phosphate. Because phosphate is rapidly incorporated into the new cells, this can contribute to the severity of the hypophosphatemia. Drugs that cause increased renal elimination of phosphate include diuretics (acetazolamide and osmotic diuretics), glucocorticoids, and sodium bicarbonate.

Rapid refeeding of malnourished patients with high-carbohydrate, high-calorie diets with inadequate amounts of supplemental phosphate can result in severe symptomatic hypophosphatemia. This phenomenon is especially prevalent in patients with other underlying risk factors for the development of hypophosphatemia, such as alcoholism. The etiology of severe hypophosphatemia associated with hyperalimentation and nutritional recovery can be separated into two phases: acute, rapid hypophosphatemia secondary to intracellular shifts of phosphate resulting from glucose-induced insulin secretion; and the gradual decrease in serum phosphate concentration over 5 to 10 days secondary to tissue repair in the presence of phosphate deprivation. The development of severe hypophosphatemia secondary to hyperalimentation can be prevented by the administration of 12 to 15 mmol of phosphate per liter of hyperalimentation solution or 15 mmol per 1,000 calories (4.2 kJ) of dextrose. Transcellular shifts in phosphate also occur after parathyroidectomy, causing severe hypocalcemia and hypophosphatemia because of hungry bone syndrome (deposition of phosphate and calcium in the bone).

Severe and prolonged respiratory alkalosis (a result of hyperventilation, pain, anxiety, and sepsis) can cause hypophosphatemia. Respiratory alkalosis is thought to contribute significantly to the hypophosphatemia observed during alcohol withdrawal. Patients with diabetic ketoacidosis may present with hyperphosphatemia, the institution of therapy to correct it can cause serum phosphate concentrations to decrease rapidly as phosphate shifts back into the intracellular compartment. In addition, the acidosis associated with the diabetic ketoacidotic state can cause a decomposition of organic compounds inside the cell and a release of inorganic phosphate into the plasma and subsequently into the urine.

The combination of intracellular phosphate breakdown and the shift of phosphate into cells on initiation of treatment can lead to severe hypophosphatemia. Drugs associated with transcellular shifts in phosphate include dextrose solutions, glucagon, insulin, catecholamines, calcitonin, erythropoietic agents, and anabolic steroids.

Chronic ethanol abusers are prone to a variety of serum electrolyte disorders including hypocalcemia, hypomagnesemia, hypokalemia, and hypophosphatemia. The etiology of hypophosphatemia in the alcoholic patient is multifactorial. Malnutrition, poor dietary

intake, diarrhea, vomiting, and the use of phosphate-binding antacids can all contribute to the hypophosphatemia of alcoholism. In addition, serum phosphate concentrations may decrease after hospitalization in the alcoholic patient with the institution of dextrose-containing intravenous fluids as a result of an intracellular shift of phosphate. Hyperventilation associated with the alcohol withdrawal syndrome can also contribute to the development of hypophosphatemia. Alcoholic patients are particularly susceptible to the complications of hypophosphatemia such as rhabdomyolysis, which is often seen during withdrawal or refueling. Thus, serum phosphate concentrations should be routinely monitored in alcoholic patients.

**CLINICAL PRESENTATION**

The clinical manifestations of severe hypophosphatemia are diverse and many organ systems can be affected. It is likely that two primary biochemical abnormalities are responsible for most of the clinical manifestations of severe hypophosphatemia. First, intracellular energy stores may be decreased secondary to depletion of intracellular ATP. This can result in disruptions in cellular function. Second, reduced red blood cell 2,3-DPG concentrations are associated with a shift to the left of the oxyhemoglobin saturation curve. This shift is associated with a decrease in the release of oxygen to peripheral tissues (increased oxygen affinity for hemoglobin) and may result in tissue hypoxia. These metabolic disorders can be seen in a wide variety of organ systems.

Neurologic (CNS) manifestations of severe hypophosphatemia result in a metabolic encephalopathy syndrome. This progressive syndrome of irritability, apprehension, weakness, numbness, paresthesia, dysarthria, confusion, obtundation, seizures, and coma has been described in patients with severe hypophosphatemia. Neuropsychiatric disturbances include apathy, delirium, hallucinations, and paranoia. Peripheral neuropathy and symptoms resembling Guillain-Barré syndrome have also been reported.

Severe hypophosphatemia can result in significant dysfunction of skeletal muscle ranging from myalgia, bone pain, and weakness, with chronic hypophosphatemia, to potentially fatal rhabdomyolysis with severe acute hypophosphatemia. Laboratory evaluations can help to distinguish between chronic and acute on chronic hypophosphatemia. Elevated alkaline phosphatase, normal creatine phosphokinase, and normal to low phosphate and calcium are present in cases of chronic hypophosphatemia. In contrast, hyperkalemia, hyperuricemia, elevated blood urea nitrogen and creatinine, hypercalcemia, and myoglobinuria are often present in cases in which rhabdomyolysis complicates the acute or chronic hypophosphatemia. Hypophosphatemia can result in acute respiratory failure secondary to respiratory muscle weakness and diaphragmatic contractile dysfunction. Thus frequent assessment of serum phosphate concentration is indicated in patients at risk for respiratory failure. Likewise, adequate treatment of hypophosphatemia in respiratory failure can aid in successful weaning from the ventilator. Dysphagia and ileus have also been attributed to hypophosphatemia.

Myocardial dysfunction has been reported to be impaired in the setting of hypophosphatemia and has resulted in congestive myocardopathy. This has been reported in alcoholics, and postoperative and intensive care patients. A depletion in cardiac ATP stores has been hypothesized as the cause of this syndrome. Arrhythmias have also been reported in patients with hypophosphatemia. Because hypophosphatemia is a potentially reversible cause of heart failure, it should be considered in patients who experience an acute deterioration in ventricular function.

Hematologic manifestations of hypophosphatemia include decreased levels of 2,3-DPG, decreased red blood cell ATP, and membrane rigidity. When red blood cell ATP decreases to below 15% of normal, cells become spherocytic and rigid, and are trapped and destroyed in the spleen. Therefore, hemolysis can be a manifestation of severe hypophosphatemia. Reduction in ATP content of white blood cells can result in mobility, chemotaxis, phagocytosis, and bactericidal dysfunction. These changes can contribute to an increased risk of infection in hypophosphatemic patients. Animal studies also demonstrate platelet abnormalities in the setting of hypophosphatemia. The implications of hypophosphatemia for human platelet function, however, have not been determined.

Finally, prolonged hypophosphatemia may result in osteopenia and osteomalacia because of enhanced osteoclastic resorption of bone and limited crystalization constituents (phosphate), respectively. Glucose intolerance from hypophosphatemia caused by tissue insensitivity to insulin has also been described.

**CLINICAL PRESENTATION OF HYPOPHOSPHATEMIA**

**General**

The manifestations of hypophosphatemia depend on the chronicity and severity of the phosphate depletion. The major conditions associated with symptomatic hypophosphatemia are chronic alcoholism, intravenous hyperalimentation without adequate phosphate supplementation, and the chronic ingestion of antacids. Severe hypophosphatemia can also be seen during treatment of diabetic ketoacidosis and with prolonged hyperventilation.

**Symptoms**

- Except for the effects on mineral metabolism, the symptoms of hypophosphatemia are caused by two consequences (reduction of red cell 2,3-DPG and reduction of intracellular ATP levels), and can impact virtually all organ systems. The symptoms are predominantly neurological and can include irritability, apprehension, weakness, numbness, paresthesia, and confusion. Severe acute development of hypophosphatemia can result in seizures or coma.

**Signs**

- The initial response of bone to hypophosphatemia contributes to hypercalcemia and hypercalciuria. Prolonged hypophosphatemia can also result in rickets and osteomalacia.

- Neurologic: Severe hypophosphatemia can lead to a metabolic encephalopathy.

- Cardiopulmonary: Impaired myocardial contractility, respiratory failure secondary to ATP depletion, congestive heart failure, new onset or worsening of an existing condition.

- Musculoskeletal: Proximal myopathy, dysphagia, and ileus have been reported. Acute hypophosphatemia superimposed on preexisting severe phosphate depletion can lead to rhabdomyolysis.

- Hematologic: Alterations in the hematopoietic system can also occur, resulting in hemolysis, reduction in phagocytotic and granulocyte chemotactic ability, as well as defective clot retraction and thrombocytopenia.

**Laboratory Tests**

- Serum phosphate levels <2.4 mg/dL (<0.78 mmol/L) are indicative of hypophosphatemia; however, symptomatic hypophosphatemia typically is not evident until serum phosphate <1 mg/dL (<0.32 mmol/L).
Hypophosphatemia

**TREATMENT**

**Hypophosphatemia**

- **DESIRED OUTCOME**
  The goals of therapy are the reversal of signs and symptoms of hypophosphatemia, normalization of serum phosphate concentrations, and management of underlying conditions. Awareness of the clinical situations in which hypophosphatemia is anticipated (alcoholism, diabetic ketoacidosis, and parenteral nutrition) is of vital importance in preventing iatrogenic hypophosphatemia. The routine addition of phosphate in concentrations of 12 to 15 mmol/L to intravenous hyperalimentation solutions is of utmost importance for the prevention of severe hypophosphatemia in hospitalized patients.

- **PHARMACOLOGIC THERAPY**

**CONCLUSIONS**

Clinicians play an integral part in the management of fluid and electrolyte abnormalities. Initial treatment strategy should be based on acuity of onset and severity of symptoms. Because the etiologies of calcium and phosphate disorders are diverse, it is important to integrate the known or anticipated pathophysiologic disease course into the treatment strategy. The patient’s medication history should be comprehensively assessed to determine whether the electrolyte abnormality may be drug induced. After resolution or treatment of the calcium or phosphate disorder, the medication regimen should be evaluated periodically. This proactive interventional approach will facilitate the management of mild disorders in the community and can reduce the need for hospitalization.

Disorders of Potassium and Magnesium Homeostasis

DONALD F. BROPHY AND JANE FRUMIN

CHAPTER 60

KEY CONCEPTS

1. Potassium is the primary intracellular ion in the human body.
2. The normal serum potassium concentration range is 3.5 to 5 mEq/L (3.5–5 mmol/L).
3. Potassium regulates many biochemical processes in the body and is a key ion for electrical action potentials across cellular membranes.
4. In patients with concomitant hypokalemia and hypomagnesemia, it is imperative to correct the hypomagnesemia before the hypokalemia.
5. Potassium chloride is the preferred potassium supplement for the most common causes of hypokalemia.
6. Hyperkalemia is a common occurrence in patients with acute or chronic kidney disease.
7. Magnesium is an important cofactor for many cellular functions.
8. The normal serum magnesium concentration range is 1.4 to 1.8 mEq/L (0.70–0.90 mmol/L).
9. Hypomagnesemia is commonly caused by excessive gastrointestinal or renal magnesium wasting.
10. Hypermagnesemia is commonly observed in patients with acute or chronic kidney disease.

Potassium and magnesium are electrolytes that are responsible for numerous metabolic activities. Disorders of these electrolytes are frequently seen in both the acute care and community ambulatory care settings. Therefore, clinicians need a firm understanding of the etiology, pathophysiology, symptoms, pharmacotherapy, and monitoring of these disorders. This chapter describes the homeostatic mechanisms that are responsible for the maintenance of normal potassium and magnesium serum concentrations. The clinical disorders responsible for the development of hyperkalemia, hypermagnesemia, hypokalemia, and hypomagnesemia are also reviewed.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.
fruits, vegetables, and meats. The typical American ingests approximately 50 to 150 mEq (50–150 mmol) of potassium daily. Nearly all of this is absorbed, with only 10 to 20 mEq/day (10–20 mmol/day) eliminated in feces. The amount eliminated in the feces increases, however, in patients with diarrhea and in those with chronic kidney disease (CKD).  

The kidney is the primary route of potassium elimination. Potassium is freely filtered but almost all of it is reabsorbed passively in the proximal tubule and the thick ascending limb of the loop of Henle. Therefore urinary potassium excretion is primarily determined by potassium secretion from the luminal cells of the distal tubule and collecting duct. Although the amount of potassium filtered by the glomerulus approaches 700 mEq (700 mmol) per day, only approximately 10% to 20% is actually excreted in the urine. However, this amount can vary based on dietary intake, serum potassium concentration, and aldosterone activity. For example, more potassium is renally excreted in conditions that result in high aldosterone activity (e.g., dehydration) when the body is attempting to conserve sodium or when there is an increase in dietary potassium intake.

Hormones such as insulin, catecholamines, and aldosterone dramatically affect potassium homeostasis. Insulin is the most important hormonal mediator of potassium balance because it stimulates the cellular Na⁺-K⁺-ATPase pump to increase transport of potassium into liver, muscle, and adipose tissue. There is a complex negative feedback loop in which insulin secretion tightly regulates serum potassium concentrations: an increase of only a few tenths of a milliequivalent of potassium stimulates pancreatic insulin secretion in an attempt to prevent hyperkalemia from developing. If hyperkalemia does occur, glucagon is released from the liver to protect against insulin-induced hypoglycemia. Conversely, hyperkalemia inhibits insulin secretion, a finding that explains why some patients receiving diuretics develop hyperglycemia.

An elevation in circulating catecholamines such as epinephrine usually results in the intracellular movement of potassium by two mechanisms. They stimulate the β-receptor, which directly activates the Na⁺-K⁺-ATPase pump. Second, they stimulate glycogenolysis, which raises blood glucose concentrations, thereby increasing insulin secretion. This dual mechanism is often used therapeutically in patients with hyperkalemia to normalize serum potassium concentrations.

Aldosterone, a mineralocorticoid that is secreted from the adrenal glands in response to high serum potassium concentrations, promotes urinary potassium excretion. Aldosterone works in the distal tubule and collecting duct to promote the reabsorption of sodium and water in exchange for potassium. Aldosterone may also have extrarenal activity by stimulating cellular Na⁺-K⁺-ATPase pump activity.

Changes in acid-base status significantly affect the serum potassium concentration. For example, the infusion of metabolic inorganic acids, such as hydrochloric acid, results in an increase in serum potassium. The body compensates for excessive hydrogen ions by moving them from the serum into the cell in exchange for intracellular potassium, to maintain electroneutrality. The process by which this occurs is complex, and a cellular H⁺-K⁺-ATPase pump has been identified. The efflux of potassium into the serum can result in hyperkalemia. A commonly quoted approximation of the pH effect is that for every 0.1 unit decrease in pH, there is a corresponding increase in serum potassium of 0.6 to 0.8 mEq/L (0.6–0.8 mmol/L) (with a wide range of 0.2–1.7). This is often referred to as false hyperkalemia because there is not a true excess of total-body potassium. Metabolic acidosis associated with lactic acidosis and ketoacidosis, does not result in hyperkalemia, because both cations and anions enter the cell, thus maintaining electroneutrality. Respiratory acidosis also does not significantly affect the serum potassium concentration.

Conversely, metabolic alkalosis has been associated with hypokalemia. As a result of a net loss of hydrogen ion from the serum, intracellular hydrogen ions enter the serum to increase the acidity of the blood. To maintain electroneutrality extracellular potassium ions are shifted intracellularly. This creates a relative deficiency of potassium in the serum. Serum potassium decreases approximately 0.6 mEq/L (0.6 mmol/L) for each 0.1 unit increase in blood pH. This is frequently termed false hypokalemia because there is not a true deficiency in total-body potassium.

Finally, hyperosmolality can result in enhanced movement of potassium from the cell into the extracellular fluid. This occurs most likely because of the associated cell shrinkage and water loss, which increases the intracellular-to-extracellular potassium gradient. This is seen most commonly in conditions such as diabetic ketoacidosis. Conversely, hypoosmolality does not seem to affect potassium distribution.

**HYPOKALEMIA**

**Epidemiology**

Hypokalemia (defined as a serum potassium concentration <3.5 mEq/L [<3.5 mmol/L]) is a commonly encountered electrolyte abnormality in clinical practice. Hypokalemia can be categorized as mild (serum potassium 3.1–3.5 mEq/L [3.1–3.5 mmol/L]), moderate (serum potassium 2.5–3.0 mEq/L [2.5–3.0 mmol/L]), or severe (<2.5 mEq/L [<2.5 mmol/L]). When hypokalemia is detected, a diagnostic workup that evaluates the patient’s comorbid disease states and concomitant medications should be initiated. Hypokalemia is virtually nonexistent in healthy adults. This is due in part to the relatively high potassium content in the typical Western diet as well as the body’s effective potassium-sparing mechanisms, which tightly regulate the serum potassium concentration. However it has been estimated that as many as 50% of patients who receive thiazide or loop diuretics have serum potassium concentrations less than 3.5 mEq/L (3.5 mmol/L).

**Etiology and Pathophysiology**

Hypokalemia results when there is a total-body potassium deficit, or when serum potassium is shifted into the intracellular compartment. Total-body deficits occur in the setting of poor dietary intake of potassium, or when there are excessive renal and gastrointestinal losses of potassium.

Maintaining a consistent dietary intake of potassium is important because the body has no effective method for storing potassium. At steady state, potassium excretion matches potassium intake; approximately 90% of ingested potassium is renally excreted, whereas 10% is excreted in feces. This underscores the importance of eating a well-balanced diet. Elderly patients with chronic diseases and those undergoing surgery are at increased risk for developing hypokalemia because of insufficient intake or losses resulting from surgery.

Many drugs can cause hypokalemia by a variety of mechanisms including intracellular potassium shifting and increased renal or stool losses (Table 60–1). The most common cause of drug-induced hypokalemia is loop and thiazide diuretic administration as these agents inhibit renal sodium reabsorption, which results in increased sodium delivery to the distal tubule. Consequently, hypokalemia develops because the distal tubule selectively reabsorbs sodium, and excretes potassium down its concentration gradient. Second, because diuretics result in volume contraction, aldosterone is secreted which further promotes the renal excretion of potassium. If concomitant potassium supplements are not provided to patients receiving loop and thiazide diuretics, mild to moderate hypokalemia is inevitable.

The second most common etiology of hypokalemia is excess loss of potassium-rich GI fluid as a result of diarrhea and/or
vomiting. The typical potassium loss in feces is approximately 10 mEq (10 mmol) per day. In diarrheal states, this amount increases proportionally with the volume of stool output. Vomiting also accounts for substantial potassium losses, which have been estimated to be as high as 30 to 50 mEq (30–50 mmol) per liter of vomitus. Metabolic alkalosis can also occur in cases of severe diarrhea and vomiting as a result of loss of these bicarbonate-rich fluids. This causes an intracellular shifting of potassium, which lowers the serum concentration of potassium even further. Prolonged diarrhea and vomiting can significantly affect children and elderly patients because their kidneys are unable to effectively maintain adequate fluid status.

**Hypomagnesemia**, which is present in more than 50% of cases of clinically significant hypokalemia, contributes to the development of hypokalemia because it reduces the intracellular potassium concentration and promotes renal potassium wasting. While the precise mechanism of the accelerated renal loss is unknown, many believe that the intracellular potassium concentration may decrease because hypomagnesemia impairs the function of the Na⁺-K⁺-ATPase pump thereby promoting K⁺ wasting. Alternatively, the combination of increased sodium delivery to the distal tubule, elevated aldosterone concentrations, and hypomagnesemia may cause the renal outer medullary potassium channels to excrete potassium. What is clear is that hypokalemia and hypomagnesemia often coexist as a result of drugs (diuretic administration) or disease states (diabetes). When concomitant hypokalemia and hypomagnesemia occur, the magnesium deficiency should be corrected first, otherwise full repletion of the potassium deficit is difficult.

**TREATMENT**

**Hypokalemia**

**DESIRE OUTCOME**

The goals of hypokalemia management are to prevent its development, treat serious life-threatening complications, normalize the serum potassium concentration, identify and correct the underlying cause of hypokalemia, and finally prevent overcorrection of the serum potassium concentration.

**GENERAL APPROACH TO THERAPY**

The general approach to therapy depends on the degree and rapidity with which hypokalemia developed and the presence of symptoms. Serum potassium concentrations between 3.5 and 4 mEq/L (3.5 and 4 mmol/L) are a sign of early potassium depletion. No pharmacologic therapy is recommended at this point; however, these patients should be encouraged to increase their dietary intake of potassium-rich foods. When the serum potassium concentration is between 3.0 and 3.5 mEq/L (3.0 and 3.5 mmol/L), it is debatable whether pharmacologic therapy should be initiated. Oral potassium supplementation should be initiated in patients with underlying cardiac conditions that predispose them to cardiac arrhythmias. This includes patients receiving concomitant digoxin therapy. Patients with serum potassium concentrations below 3.0 mEq/L (3.0 mmol/L) should always be treated to achieve values between 4.0 and 4.5 mEq/L (4.0 and 4.5 mmol/L). In asymptomatic patients, oral therapy is the preferred route of administration. Intravenous (IV) potassium can be necessary in symptomatic patients with severe depletion, or in patients who are intolerant to oral supplementation. In patients with concomitant moderate to severe hypomagnesemia, the magnesium deficit should be corrected before potassium supplementation, to prevent refractory hypokalemia.

**NONPHARMACOLOGIC THERAPY**

Various nonpharmacologic therapies have been used to prevent and treat hypokalemia. The best and most abundant source of potassium supplementation comes from dietary sources, in particular, fresh fruits and vegetables, fruit juices, and meats. Table 60–2 lists foods that are excellent sources of potassium. Salt substitutes that contain potassium chloride are another effective, inexpensive source of potassium. Increased dietary intake of foods with high potassium content however is not recommended long term for many patients because it can add unwanted calories to the patient’s diet. Moreover, dietary potassium is almost entirely coupled with...

phosphate, rather than chloride, so it is not as effective in correcting potassium loss associated with hypochloremic conditions such as vomiting, nasogastric suctioning, and diuretic therapy.\(^{13}\)

PHARMACOLOGIC THERAPY

Formal guidelines for potassium supplementation were last published by the National Council on Potassium in Clinical Practice in 2000 (Table 60–3).\(^ {13}\) These guidelines provide a comprehensive framework for potassium administration as a prophylactic and therapeutic replacement in many distinct patient populations. When deciding how to design the optimal regimen one must consider: (1) the patient’s normal baseline potassium concentration; (2) underlying medical conditions that can affect potassium balance; (3) concomitant medications that can affect potassium balance; (4) the patient’s dietary and salt intake; and (5) the patient’s ability to comply with the therapeutic regimen.\(^ {13}\)

A general rule for potassium replacement is that for every 1 mEq/L (1 mmol/L) decrease of potassium below 3.5 mEq/L (3.5 mmol/L), there is a corresponding total-body potassium deficit of 100 to 400 mEq (100–400 mmol). Because of the wide variance in projected deficits, each patient’s therapy must be individualized and adjustments made on the basis of the patient’s signs, symptoms, and frequent measurements of serum potassium. In patients receiving chronic loop or thiazide diuretic therapy, 40 to 100 mEq (40–100 mmol) of oral potassium supplementation can correct mild to moderate potassium deficits. Doses up to 120 mEq (120 mmol) can be required in more severe deficiencies. When providing oral potassium supplementation, the total daily dose should be divided into three to four doses to minimize the development of GI side effects. Patients receiving diuretics can become chronically hypokalemic and can benefit from combination potassium-sparing diuretic therapy.

CLINICAL CONTROVERSY

The replacement of potassium intravenously can be accomplished by IV piggyback or Buretrol administration. A pharmacist usually prepares the potassium IV piggyback, double checks the concentration and fluid, and then dispenses the final product to the medical unit. However, with Buretrol administration, essentially any clinician (e.g., nurse or physician) can prepare the solution on the medical unit and infuse the potassium solution into the patient. The Joint Commission and the United States Pharmacopeia 797 Standards now advocate that all parenteral products be compounded in a sterile, laminar flow environment, and be double-checked by a pharmacist to assure patient safety. Many hospitals to date have not adapted these recommendations, which were developed to improve patient safety.

Whenever possible, potassium supplementation should be administered by mouth. Three salts are available for oral potassium supplementation: chloride, phosphate, and bicarbonate. Potassium phosphate should be used when patients are both hypokalemic and hypophosphatemic; potassium bicarbonate is most commonly used when potassium depletion occurs in the setting of metabolic acidosis. Potassium chloride, however, is the primary salt form used because it is the most effective treatment for the most common causes of potassium depletion (i.e., diuretic-induced and diarrhea-induced) as these conditions are associated with potassium and chloride losses.

TABLE 60-3  General Consensus Guidelines for Potassium Replacement

<table>
<thead>
<tr>
<th>Guideline</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Potassium replacement therapy should accompany dietary consumption of potassium-rich foods.</td>
<td>Potassium-rich foods often cannot completely replace potassium associated with chloride losses (vomiting, diuretics, or nasogastric suction) because it is almost entirely coupled to phosphate. Furthermore, increasing dietary intake of these foods can lead to unwanted weight gain. A high-sodium diet often results in excessive urinary potassium excretion. These conditions promote excessive renal and GI potassium loss.</td>
</tr>
<tr>
<td>Potassium replacement is recommended for sodium sensitive and hypertensive patients.</td>
<td>Clinicians should be aware of the factors that result in transcellular potassium shifts. Monitoring 24-hour urinary potassium excretion can be necessary in high-risk patients. Microencapsulated products have no bitter smell or aftertaste and have much better GI tolerance. Regimens should be made as simple as possible to follow.</td>
</tr>
<tr>
<td>Potassium replacement is recommended in patients who are subject to vomiting, diarrhea, or diuretic/laxative abuse.</td>
<td></td>
</tr>
<tr>
<td>Potassium supplementation is best administered orally in divided doses over several days to achieve full repletion.</td>
<td></td>
</tr>
<tr>
<td>Laboratory measurement of serum potassium is convenient but not always accurate.</td>
<td></td>
</tr>
<tr>
<td>Patient adherence to potassium replacement can be increased with compliance-enhancing regimens.</td>
<td></td>
</tr>
<tr>
<td>A potassium dosage of 20 mEq/day (20 mmol/day) is usually sufficient to prevent hypokalemia from occurring. Doses of 40–100 mEq (40–100 mmol) are usually sufficient to treat hypokalemia.</td>
<td></td>
</tr>
</tbody>
</table>
Potassium chloride can be administered in either tablet or liquid formulations (Table 60–4). The liquid forms are generally less expensive; however, patient compliance can be low because of their strong, unpleasant taste. Two sustained-release solid dosage forms are currently available in the United States: a wax-matrix formulation, and a microencapsulated formulation. The microencapsulated tablet is generally preferred because it disintegrates better in the stomach and is associated with less GI irritation. Intravenous potassium use should be limited to: (1) severe cases of hypokalemia (serum concentration <2.5 mEq/L [<2.5 mmol/L]); (2) patients exhibiting signs and symptoms of hypokalemia such as ECG changes or muscle spasms; or (3) patients unable to tolerate oral therapy. Intravenous supplementation is more dangerous than oral therapy because it is more likely to result in hyperkalemia, phlebitis, and pain at the site of infusion.

The vehicle in which IV potassium is administered is important. Whenever possible, potassium should be prepared in saline-containing solutions (e.g., 0.9% or 0.45% sodium chloride [NaCl]). Dextrose-containing solutions stimulate insulin secretion, which can cause intracellular shifting of potassium, worsening the patient’s hypokalemia, and should be avoided whenever possible. Generally, 10 to 20 mEq (10–20 mmol) of potassium is diluted in 100 mL 0.9% NaCl for IV administration. These concentrations are safe when administered through a peripheral vein over one hour. When infusion rates exceed 10 mEq/h (10 mmol/h), ECG monitoring should be performed to detect cardiac changes. The serum potassium concentration should be evaluated following the infusion of each 30 to 40 mEq (30–40 mmol) to direct further potassium replacement requirements. Multiple doses of potassium can be repeated as needed until the serum potassium concentration normalizes. To allow adequate time for the potassium to equilibrate between the intra- and extracellular spaces, the clinician should wait at least 30 minutes from the end of each infusion before obtaining a serum concentration. Care should be taken to avoid sampling from the same line in which the potassium was infused, as this can result in a spuriously high potassium concentration.

In cases of severe potassium depletion, patients can require as much as 300 to 400 mEq/day (300–400 mmol/day). In this instance, it is common practice to dilute 40 to 60 mEq (40–60 mmol) in 1,000 mL 0.45% NaCl and infuse at a rate not exceeding 40 mEq/h (40 mmol/h). This should be performed in an intensive care unit under continuous ECG monitoring. Because of the high potassium concentration, and the risk for burning pain and peripheral venous sclerosis, the infusion should be through a central venous catheter into a large vein (e.g., superior vena cava) but care must be taken not to place the tip of the catheter into the right atrium. Directly delivering high potassium concentrations into the heart can result in cardiac arrhythmias. Given the volume required to infuse this dose of potassium, this infusion strategy might be impractical in certain clinical situations (e.g., patients requiring fluid restriction). A reasonable alternative is to split the potassium dose between the oral and IV routes. For example, if a symptomatic patient requires 120 mEq (120 mmol) of potassium, the clinician can give 60 mEq (60 mmol) as the immediate-release potassium liquid, and the other 60 mEq (60 mmol) can be given through the IV route (20 mEq/100 mL/h [20 mmol/100mL/h] in three doses). When giving large potassium doses, serum monitoring should be performed following the administration of half the dose to guide the clinician as to the need for additional potassium. This can also help avoid the development of hyperkalemia.

In the rare circumstances when cardiac arrest from hypokalemia is imminent, IV bolus dosing of potassium 10 mEq (10 mmol) over 5 minutes can be initiated and repeated once, if necessary.  

### ALTERNATIVE THERAPIES

Potassium-sparing diuretics are an alternative to chronic exogenous potassium supplementation, especially when patients are concomitantly receiving drugs that are known to deplete potassium (e.g., diuretics or amphotericin B). Spironolactone inhibits the effect of aldosterone in the distal convoluted tubule, thereby decreasing potassium elimination in the urine. Spironolactone is especially effective as a potassium-sparing agent in patients with primary or secondary hyperaldosteronism. Amiloride and triamterene act by an aldosterone-independent mechanism; however, the precise mechanism of their potassium sparing is unknown.

Spironolactone is available as 25-mg, 50-mg, and 100-mg tablets. The usual starting dose is 25 to 50 mg daily, and can be titrated to a maximum dose of 400 mg/day. The potassium-retaining effects generally take approximately 48 hours to occur. Important side effects include hyperkalemia, gynecomastia, breast tenderness, and impotence in men.

Trienterene is available as 50-mg and 100-mg capsules. The usual starting dose is 50 mg twice daily, which can be titrated to 100 mg twice daily. Triamterene 50 mg is available as a combination product with hydrochlorothiazide 25 mg and is commonly used for the treatment of hypertension. Common side effects include hyperkalemia, sodium depletion, and metabolic acidosis.

Amiloride is available as a 5-mg tablet. The usual starting dose is 5 mg daily; however, 10 mg can be given in those with severe hypokalemia. This is also available as a combination product with hydrochlorothiazide 50 mg. The most common side effects are hyperkalemia and metabolic acidosis.

Generally, concomitant use of potassium supplementation with potassium-sparing diuretics is not necessary. There is a significant risk of hyperkalemia during combination therapy, especially in patients with underlying renal insufficiency or diabetes mellitus.

While there have been no pharmacoeconomic evaluations of the different pharmacotherapeutic alternatives to manage hypokalemia, the most convenient source of chronic potassium supplementation is appropriate dietary intake of potassium-rich foods.

### EVALUATION OF THERAPEUTIC OUTCOMES

Serum potassium concentrations should be monitored regularly while the patient is receiving potassium supplementation. For patients receiving prophylactic potassium supplementation during diuretic therapy, the serum potassium and magnesium concentrations, as well as renal function should be monitored every 1 to 2 months in stable patients. In hospitalized patients receiving oral therapy for mild hypokalemia, the potassium concentration should be monitored every 2 to 3 days. Generally, the

</table>
potassium concentration begins to increase within 72 hours. If it does not increase by at least 1 mEq/L (1 mmol/L) within 96 hours, the clinician should suspect concomitant magnesium depletion. Patients receiving IV potassium supplementation require close ECG monitoring if the infusion rate is >20 mEq/h (>20 mmol/h). Doses greater than this should be administered only in the presence of continuous ECG monitoring. Additionally, the patient should have potassium concentrations obtained halfway through, and 30 minutes following completion of the total potassium dose to guide further potassium dosing. Finally, the patient should be assessed for adverse effects such as pain at the infusion site or phlebitis.

**HYPERKALEMIA**

Hyperkalemia, defined as a serum potassium concentration greater than 5.0 mEq/L (>5.0 mmol/L), can be further classified according to its severity: mild hyperkalemia (5.1–5.9 mEq/L [5.1–5.9 mmol/L]), moderate hyperkalemia (6.0–7.0 mEq/L [6.0–7.0 mmol/L]), and severe hyperkalemia (>7 mEq/L [>7 mmol/L]).

**Epidemiology**

Hyperkalemia is much less common than hypokalemia. In fact, if all patients with acute and chronic kidney disease were excluded, the true prevalence of hyperkalemia would be insignificant. The incidence of hyperkalemia in hospitalized patients is highly variable, and reports have ranged from 1.4% to 10%. Most cases of hyperkalemia are the result of overcorrection of hypokalemia with IV potassium supplementation. Severe hyperkalemia occurs more commonly in elderly patients with renal insufficiency who receive chronic oral potassium supplementation.

**Etiology and Pathophysiology**

Hyperkalemia develops when potassium intake exceeds excretion (true hyperkalemia) (i.e., elevated total-body stores), or when the transcellular distribution of potassium is disturbed (i.e., normal total-body stores). The four primary causes of hyperkalemia—(1) increased potassium intake, (2) decreased potassium excretion, (3) tubular unresponsiveness to aldosterone, and (4) redistribution of potassium into the extracellular space—are discussed below.

**Hyperkalemia Associated with Increased Potassium Intake**

Hyperkalemia in this setting is almost always associated with renal insufficiency. Patients with stage 4 or 5 CKD and dialysis patients who are noncompliant with dietary potassium restrictions often present with life-threatening hyperkalemia. Many of these patients do not realize that fresh fruits and vegetables contain large amounts of potassium. Anecdotally, in many dialysis centers the incidence of hyperkalemia peaks during the summer months, when fresh garden produce is available. Another common dietary source associated with the development of hyperkalemia is potassium chloride salt substitutes. Many dialysis patients are instructed to use salt substitutes to avoid excessive sodium intake in an attempt to control volume overload. These patients unwittingly become hyperkalemic because these products contain approximately 10 to 15 mEq (10–15 mmol) potassium per gram, or 200 mEq (200 mmol) per tablespoon. Finally, many over-the-counter herbal and alternative medicine products may contain significant concentrations of potassium.

It is essential for patients with CKD to receive education regarding dietary sources of potassium as well as information on the potassium content of herbal products because the ingestion of these can lead to hyperkalemia.

Hyperkalemia Associated with Decreased Renal Potassium Excretion

The kidneys excrete 80% of the daily potassium intake. Therefore, when the kidney is unable to excrete potassium appropriately, as in acute kidney injury (AKI) and stage 4 to 5 CKD, potassium is retained and often results in hyperkalemia. Finally, many drugs can inhibit the kidney’s ability to excrete potassium by inhibiting aldosterone and thus contribute to an increase in serum potassium concentrations.

Severe hyperkalemia is more common in AKI than in CKD because patients are often hypercatabolic and can have underlying disorders, such as rhabdomyolysis or tumor lysis syndrome, which result in release of potassium from injured or lysed cells. Severe hyperkalemia is rare in stable CKD patients, perhaps because of enhanced GI and renal potassium excretion.

Data suggest that hyperkalemia directly stimulates renal K’ excretion through an effect that is independent of, and additive to, that of aldosterone. Although the overall incidence of hyperkalemia is higher in patients with CKD when compared to patients without CKD, due to these adaptive mechanisms and their decreased susceptibility to cardiac effects of chronic hyperkalemia, it has been associated with a lower mortality rate. Renal excretion of potassium is also inhibited by various endocrinologic disorders, including adrenal insufficiency, Addison’s disease, and selective hypoaldosteronism. All of these disorders involve a decreased production of aldosterone, which results in the retention of potassium.

Several drugs have profound effects on the kidney’s ability to regulate potassium. Four drug classes in particular have specific effects on the kidney: angiotensin-converting enzyme inhibitors (ACEIs), angiotensin-II receptor blockers (ARBs), potassium-sparing diuretics, and prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs (NSAIDs).

Although hyperkalemia with these drugs is typically dose dependent, the rates of hyperkalemia have been reported to range from 5% to 10% in most clinical trials. Other commonly used drugs that can cause hyperkalemia are digoxin, cyclosporine, tacrolimus, trimethoprim-sulfamethoxazole, heparin, and pentamidine.

**Tubular Unresponsiveness to Aldosterone**

Certain medical conditions, such as sickle cell anemia, systemic lupus erythematosus, and amyloidosis, can produce a defect in tubular potassium secretion, possibly as the result of an alteration in the aldosterone-binding site. The exact mechanism of the tubular unresponsiveness is unknown.

**Redistribution of Potassium into the Extracellular Space**

The eflux of potassium from within the cell into the extracellular fluid, which is associated with no change in total-body potassium stores, is to be expected in the presence of metabolic acidosis, diabetes mellitus, chronic renal failure, or lactic acidosis. β-Blockers can also result in a transcellular potassium shift.

The serum potassium concentration can also be falsely elevated in some conditions, and not reflect the actual in vivo potassium concentration. This is termed pseudohyperkalemia. Pseudohyperkalemia occurs most commonly in the setting of extravascular hemolysis of red blood cells. When a blood specimen is not processed promptly and cellular destruction occurs, intracellular potassium is released into the serum. Pseudohyperkalemia can also occur in conditions of thrombocytosis or leukocytosis. If severe hyperkalemia is found in a patient who is asymptomatic with an otherwise normal laboratory report, the hyperkalemia is most likely pseudohyperkalemia, and a repeat blood sample should be evaluated. Truly elevated potassium concentrations are normally associated with other
laboratory abnormalities, such as low carbon dioxide (acidosis) or elevated blood urea nitrogen and creatinine concentrations (indicating renal insufficiency).

### General Presentation of Hyperkalemia

- Related to the effects of excessive potassium on neuromuscular, cardiac, and smooth muscle cell function.
- Frequently asymptomatic.
- The patient might complain of heart palpitations or skipped heartbeats.

### Signs
- ECG changes (see Fig. 60–1 for description).

### Laboratory Tests
- Serum potassium concentration >5.5 mEq/L (>5.5 mmol/L).

### Treatment

#### Hyperkalemia

<table>
<thead>
<tr>
<th>DESIRED OUTCOME</th>
</tr>
</thead>
<tbody>
<tr>
<td>The goals of therapy for the treatment of hyperkalemia are to antagonize adverse cardiac effects, reverse signs and symptoms that are present, and return the serum and total-body stores of potassium to normal. The design of the treatment approach is determined by the severity of hyperkalemia, the rapidity of its development, and the patient’s clinical condition. Although ECG changes are directly proportional to the plasma potassium concentration and its rate of increase, they may not be present in all patients. In contrast, ventricular fibrillation may be the first cardiac manifestation of hyperkalemia in some patients. Asymptomatic patients with mild hyperkalemia usually require no specific therapy other than dietary education to control intake, and monitoring of serum potassium daily if an inpatient or weekly if an outpatient to assure resolution. Severe hyperkalemia (&gt;7 mEq/L [&gt;7 mmol/L]) or moderate hyperkalemia (6.0–6.9 mEq/L [6.0–6.9 mmol/L]), when associated with clinical symptoms or ECG changes, requires immediate treatment. Initial treatment of severe and moderate symptomatic hyperkalemia is focused on antagonism of the cardiac membrane actions of hyperkalemia (e.g., with calcium). Secondly, one should attempt to decrease extracellular potassium concentration by promoting its intracellular movement (e.g., with glucose, insulin, β-receptor agonists, or sodium bicarbonate) or enhance its removal from the body by hemodialysis, the oral administration of cation-exchange resins, and/or the use of loop diuretics. In any case, the underlying cause of hyperkalemia should be identified and reversed, and exogenous potassium must be withheld.</td>
</tr>
</tbody>
</table>

#### General Approach to Treatment

A general treatment approach for patients with hyperkalemia is outlined in Figure 60–2. In patients who have acute ECG changes, IV calcium should be administered to prevent or treat any cardiac manifestations of hyperkalemia. At the same time, the serum potassium concentration should be rapidly decreased to <5.0 mEq/L (<5.0 mmol/L) within minutes by administering drugs that cause an intracellular shift, followed by those that increase the elimination of potassium from the body. If the patient is asymptomatic, rapid correction may not be necessary, and will likely depend on the clinical context associated with the rise in serum potassium concentration. If one anticipates the need to reduce total-body potassium stores, an ion exchange resin (e.g., sodium polystyrene sulfonate [SPS]) that results in removal of potassium from the body over several hours to days should be initiated shortly after the emergent care has been instituted.

#### Nonpharmacologic Therapy

A recent study suggested that hemodialysis patients who ingested foods supplemented with glycyrrhetinic acid, the active ingredient in licorice, were better able to maintain plasma potassium concentrations within the normal range compared to hemodialysis patients given placebo. Glycyrrhetinic acid inhibits the enzyme 11β-hydroxy-steroid dehydrogenase II, thereby increasing cortisol availability in the colon. The net result is enhanced potassium elimination in the feces. Other nonpharmacologic therapies, specifically available for dialysis-dependent patients with end-stage renal disease (ESRD), are the institution of intermittent dialysis or hemofiltration therapy.
Therapeutic Alternatives for the Management of Hyperkalemia

**PHARMACOLOGIC THERAPY**

Various drug therapies have been used to lower the serum potassium concentration. The optimal regimen for a given patient is dependent on the rapidity and degree of lowering that is necessary. Table 60–5 provides an overview of the available therapies, and their respective onset and duration of action one can expect.

While specific treatment recommendations vary, it is generally accepted that asymptomatic patients with potassium concentrations <6.0 mEq/L (6.0 mmol/L) can be treated conservatively. In patients with normal renal function, or those with stage 3 or 4 CKD, this typically involves the administration of furosemide to promote urinary potassium excretion. When given IV at a dosage of 40 to 80 mg, urine flow usually increases within minutes and persists for approximately 4 to 6 hours. Close monitoring of the patient’s volume status and other electrolyte concentrations is required while the patient is receiving furosemide or other loop diuretic therapy. Alternatively, SPS (Kayexalate) a cation-exchange resin can be administered orally or rectally by enema. SPS is available in powder form or prepackaged as a 33% sorbitol suspension. The oral route is more effective than the enema and is better tolerated by the patient. As the resin passes through the intestines, each gram of SPS exchanges 1 mEq (1 mmol) of sodium for 1 mEq (1 mmol) of potassium ions, which are in a relatively higher concentration in the large intestine. The onset of action of SPS is within 1 hour, and it can be repeated every 4 hours as needed. The sorbitol component of the suspension promotes the excretion of the cationically modified potassium exchange resin by inducing diarrhea. The usual oral SPS dose is 15 to 60 g in the 33% sorbitol suspension. A retention enema prepared by mixing 60 to 100 g SPS in 100 to 200 mL of a 30% sorbitol or 10% dextrose suspension warmed to body temperature will usually remove 0.5 mEq of potassium per gram of SPS.27 The enema may be retained in the rectum for several hours as tolerated by the patient.

In symptomatic patients, or in those with severe hyperkalemia, emergency care is indicated. Initial therapy in this setting is the administration of IV calcium chloride or gluconate 1 g to protect the heart from life-threatening arrhythmias.24 Calcium antagonizes the cardiac membrane effect of hyperkalemia by reducing the electrical threshold potential for cardiac myocytes and reverses ECG changes within minutes. Its duration of action is 30 to 60 minutes, and it can be repeated as needed based on ECG findings. Intravenous calcium can be given as either the chloride or gluconate salt; each is available as a 10% solution by weight. Calcium chloride provides approximately three times more calcium than equal volumes of the gluconate salt; however, it can cause tissue necrosis if extravasation occurs. For this reason, calcium gluconate is more commonly administered, with the standard dose being 10-mL IV bolus over 5 to 10 minutes.

Rapid correction of hyperkalemia may necessitate the administration of drugs that result in an intracellular shift of potassium, such as insulin and dextrose, sodium bicarbonate, and a β2-adrenergic receptor agonist (e.g., albuterol or terbutaline). The treatment of choice depends on the underlying medical disorders accompanying hyperkalemia. For example, in patients with concomitant metabolic acidosis, a sodium bicarbonate bolus or infusion of 50 to 100 mEq (50–100 mmol) is the preferred therapy (see Chapter 61 for additional information). Sodium bicarbonate helps to correct the metabolic acidosis by raising the extracellular pH, in addition to causing a rapid intracellular potassium shift. It should be noted that sodium bicarbonate is much less effective when hyperkalemia is not related to metabolic acidosis.

K+ potassium ion; Na+, sodium ion; SC, subcutaneous.
to metabolic acidosis. Sodium bicarbonate is also less effective in patients with ESRD, in whom a decrease in serum potassium may not be seen for as long as 4 hours. Sodium bicarbonate can also lead to sodium and volume overload in patients with stage 4 or 5 CKD. Administration of a fast-acting (e.g., Insulin Lispro) or regular insulin (5–10 units IV and dextrose (10% or 50%) is an effective method of reducing potassium. Insulin increases the activity of the Na⁺-K⁺-ATPase pump, thereby intracellularly shifting potassium. Glucose should be given with insulin unless the serum glucose is >250 mg/dL (>13.9 mmol/L) because hypoglycemia can develop as a result of the effects of the insulin therapy. An IV bolus of 10 units of regular insulin and 25 g of dextrose usually lowers the serum potassium concentration by 0.6 mEq/L (0.6 mmol/L) in dialysis-dependent patients. β₂-Adrenergic agonists have a dual mechanism for lowering serum potassium. First, they stimulate the Na⁺-K⁺-ATPase pump to promote intracellular potassium uptake. Second, they stimulate pancreatic β-receptors to increase insulin secretion. Albuterol can be administered via IV (0.5 mg given over 15 minutes) or via nebulizer (10–20 mg nebulized over 15 minutes); however, it should be noted that injectable albuterol is not available in the United States. In ESRD patients, decreases in plasma potassium concentration of 0.6 mEq/L (0.6 mmol/L) and 1.0 mEq/L (1.0 mmol/L) can be anticipated after inhalation of 10 mg and 20 mg of albuterol, respectively. Of note, the doses of inhaled albuterol used for hyperkalemia are at least 4 times higher than those typically used for bronchospasm. There are important limitations with albuterol therapy, most notably variable bioavailability via the inhaled route (leading to potential over- or under-dosing and unpredictability of response) and second, cardiac side effects such as tachycardia which are undesirable in patients who already have an abnormal ECG. Furthermore, as many as 40% of patients may be resistant to the hypokalemic effects of albuterol and patients already receiving a nonselective β₂-receptor antagonist may not respond. Therefore, albuterol should not be used alone for the urgent treatment of hyperkalemia in CKD patients. The use of subcutaneous terbutaline in a small group of dialysis patients with hyperkalemia has also been shown to be effective.

A Cochrane Review evaluated the emergency treatment of hyperkalemia. Many of the reviewed studies were small, and not all intervention groups had sufficient data for meta-analysis to be performed. However, given these limitations, inhaled and nebulized β-agonists, and IV insulin-and-glucose were all deemed effective. The combination of nebulized β-agonists with IV insulin and glucose appeared to be more effective than either agent alone. The meta-analysis results were equivocal for IV bicarbonate, and notably, SPS was not effective by 4 hours.

A major problem with drawing conclusions from this meta-analysis is the heterogeneity of the study population. Most of the data were from nonrandomized, noncontrolled observational studies and case reports. Doses of the drugs were not standardized and follow-up was often lacking. Therefore, the clinician should exercise caution when extrapolating these findings to his or her clinical practice. This underscores the need for clinicians to be able to interpret the limitations of the published literature. Nonetheless, the Cochrane database review corroborates the approach detailed in Figure 60–2.
The majority of magnesium in the extracellular fluid is in the ionized form as only 20% is bound to serum proteins. The normal range for serum magnesium is 1.4 to 1.8 mEq/L, which is equivalent to 1.7 to 2.3 mg/dL or 0.70 to 0.95 mmol/L.\(^\text{33,34}\)

The recommended daily dietary magnesium intake for adults is approximately 420 mg/day and 320 mg/day for men and women, respectively.\(^\text{35}\) The maintenance of magnesium homeostasis depends on the balance between intake and output. Thirty percent to 40% of ingested magnesium is absorbed in the small bowel. Reductions in absorption have also been noted in the elderly and those with CKD. A small amount is present in intestinal secretions and in absorption have also been noted in the sigmoid colon. The kidneys play a major role in maintaining magnesium balance. Approximately 95% of the filtered magnesium is reabsorbed, thus in most patients less than 5% is excreted in the urine.\(^\text{36}\) Renal magnesium handling is unique in that approximately 20% of the filtered magnesium is reabsorbed in the proximal tubule; the majority of reabsorption occurs in the thick ascending limb of the loop of Henle. This explains why loop diuretics often cause profound urinary magnesium wasting. Unlike most other important electrolytes, there is no hormonal regulation of the distribution of magnesium between bone and circulating or intracellular magnesium pools. Because of this, both hypomagnesemia and hypermagnesemia commonly occur.

**HYPOMAGNESEMIA**

**Epidemiology**

Hypomagnesemia is a common problem in both ambulatory and hospitalized patients. Although the exact prevalence is difficult to estimate, it has been reported that up to 65% of intensive care unit patients are magnesium deficient.\(^\text{35}\) Although serum magnesium concentrations are not a reliable index of total-body magnesium content, they remain the primary diagnostic tool to evaluate body stores.

**Etiology and Pathophysiology**

Hypomagnesemia is usually associated with disorders of the intestinal tract or kidney.\(^\text{34}\) Drugs or conditions that interfere with intestinal absorption or increase renal excretion of magnesium can result in hypomagnesemia (Table 60–6). Decreased intestinal absorption as a result of small bowel disease is the most common cause of hypomagnesemia worldwide. These disorders include regional enteritis; radiation enteritis; ulcerative colitis; acute and chronic diarrhea; pancreatic insufficiency; and other malabsorptive syndromes; small-bowel bypass surgery; and chronic laxative abuse. Hypomagnesemia is commonly associated with alcoholism. The etiology is often multifactorial, including reduced intake, pancreatic insufficiency, chronic vomiting and diarrhea, and urinary magnesium wasting. In addition, patients who are hospitalized for acute alcohol withdrawal often receive IV glucose and can experience even greater reductions in their serum magnesium concentration.

Primary renal magnesium wasting can be caused by a defect in renal tubular magnesium reabsorption, or inhibition of sodium reabsorption in those segments in which magnesium transport follows passively. The former condition is associated with hypercalcemia, nephrolithiasis, and progressive renal disease. The latter is associated with Gitelman’s and Bartter’s syndromes.\(^\text{34}\) Much more common than these is renal magnesium wasting secondary to thiазide and loop diuretics.\(^\text{33}\) Other commonly used drugs that can cause renal magnesium wasting include aminoglycosides, amphotericin B, cyclosporine, digoxin, tacrolimus, cisplatin, pentamidine, and foscarnet.

**CLINICAL PRESENTATION OF HYPOMAGNESEMIA**

**General**

- The dominant organ systems affected by hypomagnesemia are the neuromuscular and cardiovascular systems.

**Symptoms**

- Neuromuscular symptoms such as tetany, twitching, and generalized convulsions are common.
- Cardiac symptoms include heart palpitations.
Guidelines for Treatment of Magnesium Deficiency

Common Magnesium Products and Their Elemental Mg2+, magnesium ion; NaCl, sodium chloride.

Magnesium supplementation can be given by the oral, IM, or IV route. Nearly all of the data regarding magnesium replacement therapy have been derived from reports in acutely ill, hospitalized patients. The severity of magnesium depletion and the presence of severe signs and symptoms should dictate the route of administration. Because IM administration is painful, it should be reserved for those patients with severe hypomagnesemia and limited venous access. IV bolus administration is associated with flushing, sweating, and a sensation of warmth; thus bolus administration should be avoided if possible. Additionally, because calcium forms a complex with the sulfate moiety, which is then excreted, large amounts of IV magnesium sulfate should be administered with caution to hypocalcemic patients, as it can further exacerbate calcium deficiency.

There have been no clinical trials assessing the optimal regimen for magnesium replacement, however, it is widely accepted that 8 to 12 g of magnesium sulfate be administered in the first 24 hours followed by 4 to 6 g per day for 3 to 5 days to adequately replete body stores. Even if severe magnesium depletion is present, approximately 50% of the administered dose is excreted in the urine. Consequently, magnesium replacement should be performed over 3 to 5 days, and continued supplementation should be provided for patients unable to eat and for those patients with continued magnesium wasting. Table 60–8 lists the commonly prescribed magnesium oral supplements and their respective elemental magnesium content.

**TREATMENT**

**Hypomagnesemia**

**DESIRED OUTCOME**

The treatment goals in the management of hypomagnesemia are (1) resolution of the corresponding signs and symptoms, (2) restoration of normal magnesium concentrations, (3) correction of concomitant electrolyte abnormalities, and (4) identification and correction of the underlying cause of magnesium depletion.

**GENERAL APPROACH TO TREATMENT**

Nearly all of the data regarding magnesium replacement therapy have been derived from reports in acutely ill, hospitalized patients. Magnesium supplementation can be given by the oral, IM, or IV route. Table 60–7 outlines one approach to the hypomagnesemic patient. The severity of the magnesium depletion and the presence of severe signs and symptoms should dictate the route of administration. Because IM administration is painful, it should be reserved for those patients with severe hypomagnesemia and limited venous access. IV bolus administration is associated with flushing, sweating, and a sensation of warmth; thus bolus administration should be avoided if possible. Additionally, because calcium forms a complex with the sulfate moiety, which is then excreted, large amounts of IV magnesium sulfate should be administered with caution to hypocalcemic patients, as it can further exacerbate calcium deficiency.

**THERAPEUTIC END POINTS**

**PHARMACOLOGIC THERAPY**

It is currently controversial whether all asymptomatic patients require magnesium supplementation.

Mg2+, magnesium ion; NaCl, sodium chloride.
Patients receiving oral magnesium therapy should be questioned regarding GI tolerance and the occurrence of diarrhea. Patients being treated for symptomatic severe hypomagnesemia should have their serum magnesium concentration monitored hourly until the serum concentration reaches 1.5 mEq/L (0.75 mmol/L) and the symptoms resolve. At that point, the serum magnesium concentration can be monitored every 6 to 12 hours for the next 24 hours while receiving magnesium supplementation. Once the magnesium concentration is stable in the normal range, a concentration can be obtained daily. It should be reiterated that it typically takes 3 to 5 days to fully replete total-body magnesium stores. Patients receiving oral magnesium-containing antacids or supplements should be asked regularly about the occurrence of diarrhea.

**HYPERMAGNESEMIA**

**Epidemiology**

Hypermagnesemia (serum magnesium >2 mEq/L [>1.0 mmol/L]) is a rare occurrence that is generally seen in patients with stage 4 or 5 CKD when magnesium intake exceeds the excretory capacity of the kidneys. Elderly patients are prone to hypermagnesemia because of their reduced glomerular filtration rate (GFR) and because of their tendency to consume magnesium-containing antacids and vitamins.

**Etiology and Pathophysiology**

Because absolute magnesium excretion decreases as GFR declines, serum magnesium concentrations tend to increase in patients with moderate to severe CKD. Indeed, magnesium concentrations steadily increase as the GFR decreases below 30 mL/min/1.73m² (0.29 mL/s/m²). As long as the patient maintains a normal diet, the serum magnesium concentration typically stabilizes at approximately 2.5 mEq/L (1.25 mmol/L). If patients with stage 4 or 5 CKD are taking concomitant magnesium-containing antacids, the serum concentration can approach 6 mEq/L (3 mmol/L), a value associated with signs and symptoms of toxicity. Critically ill patients with multiorgan system failure receiving enteral or parenteral nutrition are also prone to develop hypermagnesemia. Finally, the parenteral treatment of eclampsia with magnesium sulfate can lead to hypermagnesemia. Table 60–9 lists other causes of hypermagnesemia.

**Clinical Presentation**

The signs and symptoms of hypermagnesemia reflect magnesium’s action on the neuromuscular and cardiovascular systems. The main symptoms include lethargy, confusion, arrhythmias, and muscle weakness. Symptoms are rare when the serum concentration is <4 mEq/L (<2 mmol/L) (Fig. 60–3).

**FIGURE 60-3.** Clinical findings associated with hypermagnesemia. (Serum magnesium levels in mmol/L can be determined by multiplying the serum magnesium value expressed in mEq/L by 0.5.)

**TREATMENT**

**Desired Outcome**

The goals of therapy are to (1) reverse the neuromuscular and cardiovascular manifestations of hypermagnesemia, (2) decrease the magnesium concentration toward normal values, and (3) identify and treat the underlying cause of hypermagnesemia.

**Pharmacologic Therapy**

There are three primary means of treating hypermagnesemia: (1) reduce magnesium intake, (2) enhance elimination of magnesium, and (3) antagonize the physiologic effects of magnesium. The optimal treatment regimen for the management of hypermagnesemia depends on the severity of the patient’s signs and symptoms and the degree of serum concentration elevation. Intravenous elemental calcium doses of 100 to 200 mg directly antagonize the neuromuscular and cardiovascular effects of hypermagnesemia. Oral calcium is not effective because of its relatively poor bioavailability and slow onset of action. The clinical effect of calcium is immediate, but the effect is transient; hence, repeated IV doses of 100 to 200 mg of elemental calcium (e.g., 2 g of calcium gluconate) might need to be administered hourly until the signs or symptoms abate and the magnesium concentration...

is normalized. Supportive care with cardiac pacing, vasopressors, and mechanical ventilation can be necessary in life-threatening situations. In patients with normal renal function, or those with stage 1, 2, or 3 CKD, forced diuresis with saline and loop diuretics can promote magnesium elimination. An initial IV bolus of furosemide 40 mg or a similar equivalent can be used. Subsequent dosing can be determined based on the patient’s clinical response. Patients with CKD can require long-term loop diuretic therapy to maintain adequate fluid and electrolyte balance. In dialysis patients, their hemodialysis prescription should be changed to employ magnesium-free dialysate.

**EVALUATION OF THERAPEUTIC END POINTS**

Patients who are receiving IV calcium salts for the treatment of severe, symptomatic hypermagnesemia should have their serum magnesium concentration evaluated hourly until symptoms abate and the magnesium concentration decreases below 4 mg/dL (1.64 mmol/L). Furthermore, the patient should be continuously monitored to detect ECG changes. In CKD patients who can produce urine, forced diuresis with saline and furosemide should reduce the serum magnesium concentration within 6 to 12 hours. Close monitoring of the urine output and physical examination for signs of volume overload are important. Emergency hemodialysis will usually correct the hypermagnesemia within 4 hours and is a reasonable option for those who are currently receiving hemodialysis. To prevent further episodes of hypermagnesemia, the patient should receive dietary education regarding foods and beverages that contain large quantities of magnesium (Table 60–10).

In conclusion, disorders of potassium and magnesium are frequently encountered in both the acute care and community ambulatory care settings. If severe, these disorders can have catastrophic results. Clinicians should be able to identify patients at risk for these common electrolyte disorders and quickly design appropriate pharmacotherapy and monitoring regimens to optimize patient outcomes.

**ABBREVIATIONS**

ACEI: angiotensin-converting enzyme inhibitor
AKI: acute kidney injury

IV: intravenous
NSAID: nonsteroidal anti-inflammatory drug
PTH: parathyroid hormone
SPS: sodium polystyrene sulfonate

**REFERENCES**

KEY CONCEPTS

1 The kidney plays a central role in the regulation of acid–base homeostasis through the excretion or reabsorption of filtered bicarbonate (HCO$_3^-$), the excretion of metabolic fixed acids, and generation of new HCO$_3^-$.

2 Metabolic acidosis and metabolic alkalosis are generated by a primary change in the serum bicarbonate concentration. In metabolic acidosis, bicarbonate is lost or a nonvolatile acid is gained, whereas metabolic alkalosis is characterized by a gain in bicarbonate or a loss of nonvolatile acid.

3 Arterial blood gases, along with serum electrolytes, physical findings, medical and medication history, and the clinical condition of the patient, are the primary tools to determine the cause of an acid–base disorder and to design and monitor a course of therapy.

4 Renal tubular acidosis refers to a group of disorders characterized by impaired tubular renal acid handling despite normal or near-normal glomerular filtration rates. These patients often present with hyperchloremic metabolic acidosis.

5 Respiratory compensation for a primary metabolic acidosis begins rapidly (within 15–30 minutes) but does not reach a steady state for 12 to 24 hours after the onset of metabolic acidosis.

6 Primary therapy of most acid–base disorders must include treatment or elimination of the underlying cause, not just correction of the pH and electrolyte disturbances.

7 Potassium supplementation is always necessary for patients with chronic metabolic acidosis, as the bicarbonaturia resulting from alkali therapy increases renal potassium wasting.

8 Effective treatment of the underlying cause of some organic acids (e.g., ketoacidosis) can result in the regeneration of bicarbonate within hours, thus mitigating the need for alkali therapy.

9 Loss of gastric acid from vomiting or nasogastric suctioning is often responsible for the development of a metabolic alkalosis, characterized by hypochloremia and hyperbicarbonatemia.

10 Aggressive diuretic therapy can produce a metabolic alkalosis, and the accompanying hypokalemia can be serious.

11 The patient’s response to volume replacement can be predicted by the urine chloride concentration and permits the differential diagnosis of metabolic alkalosis.

12 Management of sodium chloride-resistant metabolic alkaloses usually consists of treatment of the underlying cause of mineralocorticoid excess. In patients in whom the mineralocorticoid excess cannot be corrected, chronic pharmacologic therapy can be required.

13 In most cases of acute metabolic acidosis, such as following cardiopulmonary arrest, sodium bicarbonate therapy is not indicated and can be detrimental. Blood gas analysis should guide therapy.

Acid–base disorders are common and often serious disturbances that can result in significant morbidity and mortality. This chapter reviews the mechanisms responsible for the maintenance of acid–base balance and the laboratory analyses that aid clinicians in their assessment of acid–base disorders. The pathophysiology of the four primary acid–base disturbances is presented, the therapeutic options are critiqued, and guidelines for the achievement of the desired therapeutic outcomes are presented. Because many drugs affect acid–base homeostasis and many acid–base abnormalities are potentially preventable, clinicians must anticipate drug-related problems to avoid or minimize the clinical consequences of acid base disorders, and when necessary, design appropriate treatment regimens.

ACID–BASE CHEMISTRY

An acid (in this equation, hydrochloric acid) is a substance that can donate protons (hydrogen ion [H$^+$]):

$$\text{(acid)} \text{HCl} \rightarrow \text{H}^+ + \text{chloride ion (Cl}^-)$$

A base (in this equation, ammonia [NH$_3$]) is a substance that can accept protons (hydrogen ion [H$^+$]):

$$\text{Ammonia (NH}_3\text{)} + \text{H}^+ \rightarrow \text{NH}_4^+$$ (base)

The acid–base pairs commonly encountered in clinical practice are listed in Table 61–1.
The acidity of body fluids is quantified in terms of the hydrogen ion concentration. By convention, the degree of acidity is expressed as pH, or the negative logarithm (base 10) of the hydrogen ion concentration. Thus hydrogen ion concentration and pH are inversely related. Normally, the pH of blood is maintained at 7.40 ([H⁺] of 4 × 10⁻⁷ M) with a range of 7.35 to 7.45. A pH of less than 6.7 ([H⁺] of 2 × 10⁻⁶ M), representing a five-fold increase in hydrogen ion concentration, or greater than 7.7 ([H⁺] of 2 × 10⁻⁴ M), representing a 50% decrease in hydrogen ion concentration, are considered incompatible with life.

The hydrogen ion concentration in blood may not be indicative of that in other body compartments. For example, the pH within cells, within the cerebrospinal fluid, or on the surface of bone can all be altered without causing an alteration in blood pH. Recognizing this caveat, the acid–base status of the body is usually analyzed based on measurement of blood pH. Alterations in blood pH serve as the basis for the diagnosis of acid–base disorders.

Because the dissociation of acid–base pairs is an equilibrium reaction, the relationship between hydrogen ion concentration or pH and the relative concentrations of the acid and base can be described mathematically in terms of the dissociation constant for the acid–base buffer pair. When expressed as a logarithmic relationship, where $pK$ is the negative logarithm of the dissociation constant $K$,

$$pH = pK + \log\left(\frac{[\text{base}]}{[\text{acid}]}\right)$$

### TABLE 61-1 Acid–Base Pairs

Thus, hydrogen ion concentration and pH are determined not by the absolute amounts of bicarbonate and $PCO_2$, but by their ratio. Under normal physiologic conditions, the kidneys maintain the serum bicarbonate at approximately 24 mEq/L (24 mmol/L), whereas the lungs maintain the $PCO_2$ at approximately 40 mm Hg (5.3 kPa). The normal physiologic pH is thus 7.4:

$$pH = 6.1 + \log\left(\frac{24}{0.03 \times 40}\right) \text{ (or } pH = 6.1 + \log\left(\frac{24}{0.226 \times 5.3}\right))$$

$$pH = 6.1 + 1.3 = 7.4$$

If, in response to an acid load, the serum bicarbonate concentration were to decrease to 12 mEq/L (12 mmol/L), the predicted pH would be:

$$[HCO_3^-] = 12 \text{ mEq/L (12 mmol/L)}$$
$$PCO_2 = 40 \text{ mm Hg (5.3 kPa)}$$
$$pH = 6.1 + \log\left(\frac{12}{0.03 \times 40}\right) \text{ (or } pH = 6.1 + \log\left(\frac{12}{0.226 \times 5.3}\right))$$
$$pH = 6.1 + 1.0 = 7.1$$

However, the normal respiratory response to an acid load is hyper-ventilation. As a result, if the $PCO_2$ decreased to approximately 26 mm Hg, the change in pH would be less:

$$[HCO_3^-] = 12 \text{ mEq/L (12 mmol/L)}$$
$$PCO_2 = 26 \text{ mm Hg (3.5 kPa)}$$
$$pH = 6.1 + \log\left(\frac{12}{0.03 \times 26}\right)$$
$$\text{ (or } pH = 6.1 + \log\left(\frac{12}{0.226 \times 3.5}\right))$$
$$pH = 6.1 + 1.19 = 7.29$$

Thus, the physiologic regulation of both $PCO_2$ and $[HCO_3^-]$ permit the carbonic acid/bicarbonate system to provide more effective buffering of the extracellular fluids than could be achieved on the basis of chemical buffering alone.

### REGULATION OF ACID–BASE HOMEOSTASIS

Cellular metabolism results in the production of large quantities of hydrogen that need to be excreted to maintain acid–base balance. In addition, small amounts of acid and alkali are also presented to the body through the diet. The bulk of acid production is in the form of CO₂, with the average adult producing approximately 15,000 mmol of CO₂ each day from the catabolism of carbohydrate, protein, and fat. When respiratory function is normal, the amount of CO₂ produced metabolically is equal to the amount lost by respiration, and the blood CO₂ concentration remains constant.

Digestion of dietary substances and tissue metabolism also results in the production of nonvolatile acids. These acids are derived primarily from the sulfur-containing amino acids cysteine and methionine, as well as from ingested sulfur. In addition, phosphates are generated from the metabolism of proteins and phospholipids.
Neutral substances such as glucose can also be incompletely metabolized to intermediates, such as lactic and pyruvic acid, and fatty acids can be incompletely metabolized to acetocetic acid and β-hydroxybutyric acid. These dietary and metabolic fixed acids are excreted, primarily by the kidney, to maintain acid–base homeostasis. On average, daily fixed acid excretion is approximately 0.8 mEq/kg per day (0.8 mmol/kg per day).³

Three mechanisms, each of which vary in their onset, collectively maintain acid–base balance: extracellular buffering, ventilatory regulation of carbon dioxide elimination, and renal regulation of hydrogen ion and bicarbonate excretion. Extracellular buffering occurs rapidly and is the body’s first defense against a sudden increase in hydrogen ion concentration. Hyperventilation will then result in a decrease in PCO₂, returning blood pH toward normal. Finally, the kidney will excrete the excess hydrogen ion, with the resultant return of acid–base balance to normal over a period of day(s).

EXTRACELLULAR BUFFERING

The body’s buffering system can be divided into three components: bicarbonate/carbonic acid, proteins, and phosphates. The bicarbonate buffer is the most important of the body’s buffers, because (1) there is more bicarbonate present in the extracellular fluid (ECF) than any other buffer component; (2) the supply of carbon dioxide is unlimited; and (3) the acidity of ECF can be regulated by controlling either the bicarbonate concentration or the Pco₂.

Carbonic acid represents the respiratory component of the buffer pair because its concentration is directly proportional to the Pco₂, which is determined by ventilation. Bicarbonate represents the metabolic component because the kidney may alter its concentration by reabsorption, generating new bicarbonate, or altering elimination.⁴ The bicarbonate buffer system easily adapts to changes in acid–base status by alterations in ventilatory elimination of acid (Pco₂) and/or renal elimination of base (HCO₃⁻).

The phosphate buffer system consists of serum inorganic phosphate (3.5 to 5 mg/dL [1.13–1.62 mmol/L]), intracellular organic phosphate, and calcium phosphate in bone. Extracellular phosphate is present only in low concentrations, so its usefulness as a buffer is limited; however, as an intracellular buffer, phosphate is more useful. Calcium phosphate in bone is relatively inaccessible as a buffer, but prolonged metabolic acidosis will result in the release of phosphate from bone.

Intracellular and extracellular proteins also act as buffering systems. The charged side chains of amino acids provide the buffering action. Because the concentration of protein is much greater intracellularly than extracellularly, protein is much more important as an intracellular buffer.

RESPIRATORY REGULATION

The second mechanism for maintenance of acid–base homeostasis is control of ventilation. Both the rate and depth of ventilation can be varied to allow for excretion of CO₂ generated by diet and tissue metabolism. Medullary chemoreceptors in the brainstem sense changes in Pco₂ and in pH and modulate the control of breathing. Increasing minute ventilation (the total amount of air exhaled over a 1-minute period), by increasing respiratory rate and/or tidal volume (the amount of air exhaled in one breath), will increase CO₂ excretion and decrease the blood Pco₂. Conversely, decreasing minute ventilation decreases CO₂ excretion and increases blood Pco₂. This system rapidly adjusts within minutes to changes in acid–base balance.²
Interpretation of Simple Acid–Base Disorders

Arterial

In a normal blood gas values, the arterial pH is 7.40 (7.35–7.45), the partial pressure of carbon dioxide (Paco₂) is 35–40 mm Hg (4.7–5.3 kPa), the partial pressure of oxygen (Pao₂) is 80–100 mm Hg (10.6–13.3 kPa), and the arterial blood oxygen saturation (SaO₂) is 95%. The normal values for arterial blood gases are shown in Table 61–2.

Alterations in blood pH are designated by the suffix “-emia”; acidemia is an arterial blood pH <7.35 and alkalemia is an arterial blood pH >7.45. The pathophysiologic processes that result in alterations in blood pH are designated by the suffix “-osis.” These disturbances are classified as either metabolic or respiratory in origin. In metabolic acid–base disorders, the primary disturbance is in the plasma bicarbonate concentration. Metabolic acidosis is characterized by a decrease in the plasma bicarbonate concentration whereas in metabolic alkalosis the plasma bicarbonate concentration is increased. Respiratory acid–base disorders are caused by alterations in alveolar ventilation that produce corresponding changes in the partial pressure of carbon dioxide from arterial blood (Paco₂). In respiratory acidosis, the Paco₂ is elevated; in respiratory alkalosis, it is decreased. Each disturbance has a compensatory (secondary) response that attempts to correct the HCO₃⁻: Paco₂ ratio toward normal and mitigate the change in pH (Table 61–2). Although the time course of the respiratory compensatory responses to metabolic disturbances is rapid, the metabolic compensation for respiratory disturbances is slow. As a result, respiratory disturbances are characterized as acute (minutes to hours in duration), indicating that there has not been sufficient time for metabolic compensation, or chronic (days), indicating sufficient time for metabolic compensation has elapsed.

ACID–BASE DISTURBANCES

1. Alterations in blood pH are designated by the suffix “-emia”; acidemia is an arterial blood pH <7.35 and alkalemia is an arterial blood pH >7.45. The pathophysiologic processes that result in alterations in blood pH are designated by the suffix “-osis.” These disturbances are classified as either metabolic or respiratory in origin. In metabolic acid–base disorders, the primary disturbance is in the plasma bicarbonate concentration. Metabolic acidosis is characterized by a decrease in the plasma bicarbonate concentration whereas in metabolic alkalosis the plasma bicarbonate concentration is increased. Respiratory acid–base disorders are caused by alterations in alveolar ventilation that produce corresponding changes in the partial pressure of carbon dioxide from arterial blood (Paco₂). In respiratory acidosis, the Paco₂ is elevated; in respiratory alkalosis, it is decreased. Each disturbance has a compensatory (secondary) response that attempts to correct the HCO₃⁻: Paco₂ ratio toward normal and mitigate the change in pH (Table 61–2).

Analysis of Arterial Blood Gas Data

Arterial blood gases provide an assessment of the patient’s oxygenation and acid–base status. Blood gases are measured to determine the patient’s oxygenation and acid–base status. Under normal circumstances, there is no clinically significant difference in pH between arterial and mixed venous blood. Arterial samples are designated with the letter “a” (e.g., partial pressure of oxygen from arterial blood [Pao₂] and Paco₂), whereas mixed venous samples are labeled with the letter “v” or not labeled (e.g., partial pressure of oxygen from venous blood [Pvo₂] and partial pressure of carbon dioxide from venous blood [Pvco₂]). The normal values for arterial and venous blood gases are shown in Table 61–3.

CLINICAL ASSESSMENT OF ACID–BASE STATUS

1. Blood gases are measured to determine the patient’s oxygenation and acid–base status. Under normal circumstances, there is no clinically significant difference in pH between arterial and mixed venous blood. Arterial samples are designated with the letter “a” (e.g., partial pressure of oxygen from arterial blood [Pao₂] and Paco₂), whereas mixed venous samples are labeled with the letter “v” or not labeled (e.g., partial pressure of oxygen from venous blood [Pvo₂] and partial pressure of carbon dioxide from venous blood [Pvco₂]). The normal values for arterial and venous blood gases are shown in Table 61–3. Arterial blood reflects how well the blood is being oxygenated by the lungs (an accurate measurement of Pao₂), whereas venous blood reflects how much oxygen tissues are using. Arterial blood rather than venous blood should be used whenever possible because venous blood obtained from an extremity can provide misleading information. If metabolism in the extremity is altered by hypoperfusion, exercise, infection, or some other cause, the difference in the amount of dissolved oxygen between arterial and venous blood can be dramatic. The venous pH and Pco₂ during cardiopulmonary resuscitation, might be significantly lower and higher, respectively, than the arterial pH and Pco₂. This indicates a severe tissue acidosis from CO₂ accumulation caused by hypoperfusion.

Analysis of Arterial Blood Gas Data

Arterial blood gases provide an assessment of the patient’s acid–base status. Low pH values (<7.35) indicate an acidemia, whereas high pH values (>7.45) indicate an alkalemia (Fig. 61–3). In a metabolic acidosis, the pH is decreased in association with a decreased serum bicarbonate concentration and a compensatory decrease in Paco₂. In a respiratory acidosis, the pH is decreased; the Paco₂, however, is elevated. The serum bicarbonate concentration is variable, depending on whether it is an acute disturbance (minimal increase in serum bicarbonate) or a chronic respiratory acidosis (substantial increase in serum bicarbonate). In a metabolic alkalosis, the pH is elevated in association with an increased bicarbonate concentration and a compensatory increase in Paco₂. In respiratory alkalosis, the pH is also elevated; the Paco₂, however, is decreased. As with respiratory acidosis, the metabolic compensation is variable, with a minimal decrease in serum bicarbonate in acute respiratory alkalosis and a larger decrease in [HCO₃⁻] in chronic respiratory alkalosis. Although
each measurement has a normal range (see Table 61–3), it is often easiest to consider the midpoint of each range as the normal value. This would correlate to a pH of 7.4, PaCO₂ of 40 mm Hg (5.3 kPa) and HCO₃⁻ of 24 mEq/L (24 mmol/L). Steps in acid–base interpretation are described in Table 61–4.

When arterial blood gases differ significantly from those expected on the basis of the patient’s clinical condition and previous laboratory determinations, additional venous blood samples should be drawn to assess plasma electrolyte concentrations. The bicarbonate calculated from the patient’s PaCO₂ and pH of the blood gas should be compared with the measured total CO₂ content (the amount of CO₂ gas extractable from plasma, consisting of HCO₃⁻, H₂CO₃, and Pco₂). Ordinarily, the blood gas bicarbonate value is approximately 1 to 2 mEq/L (1–2 mmol/L) less than total CO₂ content.  If these values do not correspond, the results should be interpreted with caution because the difference can reflect an error in the blood collection or storage of the sample, or in the calibration of the blood gas analyzer.

The serum anion gap (SAG), as defined below, can be used to infer whether an organic or mineral acidosis is present.

\[
SAG = [Na^+] – [Cl^-] – [HCO_3^-]
\]

To maintain electroneutrality, the total concentration of cations in the serum must equal the total concentration of anions.

\[
[Na^+] + [UCs] = ([Cl^-] + [HCO_3^-]) + [UAs]
\]

The cation concentration is equal to the sodium concentration plus that of “unmeasured” cations (UCs), predominantly magnesium, calcium, and potassium. The anion concentration is equal to the concentrations of chloride, bicarbonate, and “unmeasured” anions (UAs), including proteins, sulfates, phosphates, and organic anions. Therefore, as the result of the combination of the two equations above, the SAG can be expressed as:

\[
SAG = [UAs] – [UCs]
\]

The normal SAG is approximately 9 mEq/L (9 mmol/L), with a range of 3 to 11 mEq/L (3–11 mmol/L). This value is lower than the value of 12 mEq/L (12 mmol/L) cited in the literature in the past because of changes in the instrumentation for measurement of serum electrolytes. Increases in the anion gap to values in excess of 17 to 20 mEq/L (17–20 mmol/L) are indicative of the accumulation of unmeasured anions in ECF.

These unmeasured anions are generated as the result of the consumption of HCO₃⁻ by endogenous organic acids such as lactic acid, acetoacetic acid, or β-hydroxybutyric acid or from the ingestion of toxins such as methanol or ethylene glycol. The degree of elevation in the SAG is dependent on the clearance of the anion, as well as the multiple factors that influence HCO₃⁻ concentrations. Thus the SAG is a relative rather than an absolute indication of the cause of metabolic acidosis. The SAG can also be elevated in the metabolic acidosis because of renal failure, as the result of the accumulation of various organic anions, phosphates, and sulfates.

In hyperchloremic metabolic acidosis, bicarbonate losses from the ECF are replaced by chloride, and the SAG remains normal. This decrease in bicarbonate may be due to gastrointestinal tract losses, dilution of bicarbonate in the ECF as the result of the addition of sodium chloride solutions or chloride-containing acids. Common causes of metabolic acidosis with an increased or a normal SAG are listed in Table 61–5.

**Hyperchloremic Metabolic Acidosis**

Hyperchloremic metabolic acidosis can result from increased gastrointestinal bicarbonate loss, renal bicarbonate wasting, impaired renal acid excretion, or exogenous acid gain. Gastrointestinal...

Renal Tubular Acidosis

Renal tubular disorders can involve the proximal tubule, with a resultant failure to reabsorb filtered bicarbonate, or affect acid excretion in the distal tubule. The distal renal tubular acidoses (RTAs) are the most common, and are all characterized by impaired net acid excretion. The distal RTAs are subdivided into those that are associated with hypokalemia (type I) and those associated with hyperkalemia (type IV). Patients with classic distal (type I) RTA have impaired hydrogen ion secretion and are unable to excrete the daily acid load necessary to maintain acid–base balance. These patients are unable to maximally acidify their urine (i.e., attain urine pH <5.5), even in the face of an acid challenge. Type I RTA may be the result of a primary tubular defect or develop secondary to a wide variety of disorders including hypercalcemia, multiple myeloma, systemic lupus erythematosus, Sjögren syndrome, sickle-cell disease, and renal transplant rejection, or following the administration of amphotericin B or ingestion of toluene. The primary form of this disorder usually occurs in children and can result in severe acidosis, slowed growth, nephrocalcinosis, and kidney stones. In adults, clinical complications include osteomalacia, nephrocalcinosis, and recurrent kidney stones. The hypokalemia associated with classic distal (type I) RTA results from secondary hyposalpdrosteronism associated with volume depletion. The renal potassium wasting decreases considerably if bicarbonate therapy is administered.

The hyperkalemic distal (type IV) RTAs are a heterogeneous group of disorders characterized by hyposalpdrosteronism or generalized distal tubule defects. The most common form of type IV RTA is hyporeninemic hyposalpdrosteronism. This syndrome is most commonly associated with mild renal insufficiency caused by diabetic nephropathy, but can also be seen in a variety of other disorders, including chronic interstitial nephritis, sickle-cell disease, human immunodeficiency virus (HIV) nephropathy, and obstructive uropathy. The clinical presentation of this syndrome is often exacerbated by pharmacologic therapy with agents that can interfere with the renin-angiotensin-aldosterone axis, such as β-adrenergic blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and nonsteroidal antiinflammatory drugs. Heparin can induce the syndrome by inhibiting adrenal aldosterone biosynthesis. Patients with this form of RTA are able to maximally acidify their urine (urine pH <5.5). The primary defect in acid excretion is impaired ammoniagenesis caused by mild renal insufficiency. Hyposalpdrosteronism predisposes to the development of hyperkalemia, which results in further impairment of ammoniagenesis. Treatment to control the hyperkalemia is usually sufficient to reverse the metabolic acidosis, and mineralocorticoid replacement is frequently unnecessary.

Hypermkalemic distal (type IV) RTA resulting from generalized distal tubule defects is less common than hyporeninemic hyposalpdrosteronism but is more common than classic distal (type I) RTA. Patients with this defect have impaired tubular potassium secretion in addition to impaired urinary acidification (urine pH >5.5, despite acidemia or acid loading). Urinary obstruction is the most frequent cause of this disorder, which can also be associated with sickle-cell nephropathy, systemic lupus erythematosus, HIV nephropathy, analgesic abuse nephropathy, amyloidosis, renal transplant rejection, and chronic cyclosporine nephrotoxicity.

Proximal (type II) RTA is characterized by defects in proximal tubular reabsorption of bicarbonate. Normally, more than 85% of filtered bicarbonate is reabsorbed in the proximal tubule. Defects in proximal tubular bicarbonate reabsorption result in increased delivery of bicarbonate to the distal nephron, which has a limited capacity for bicarbonate reabsorption. As a result, at a normal serum bicarbonate concentration, the filtered bicarbonate load is
incompletely reabsorbed, and is lost in the urine. As the serum bicarbonate concentration decreases, the filtered load of bicarbonate is proportionately decreased. A new equilibrium is established in which the kidney is able to reabsorb the filtered bicarbonate load, albeit at a reduced serum bicarbonate concentration. Thus patients with proximal RTA present with a chronic, nonprogressive hyperchloremic metabolic acidosis. These patients are able to acidify their urine in response to an acid load, but develop bicarbonaturia at a reduced serum bicarbonate concentration following bicarbonate loading. The impaired bicarbonate reabsorption results in salt wasting and secondary hyperaldosteronism. Hypokalemia, which can be severe, usually develops as a result of the hyperaldosteronism and bicarbonaturia. Unlike patients with classic distal (type I) RTA, the hyperkalemia if present in proximal RTA is exacerbated by alkali replacement. Proximal RTA can develop as an isolated defect, or it can be associated with generalized proximal tubular dysfunction (Fanconi syndrome), with impaired proximal tubular glucose, phosphate, and amino acid reabsorption. Proximal RTA usually presents as an acquired disorder, secondary to a variety of diseases (amyloidosis, multiple myeloma, or nephrotic syndrome) or exposure to toxins (lead, cadmium, mercury, or outdated tetracyclines). Pharmacologic therapy with carbonic anhydrase inhibitors produces an iatrogenic form of proximal RTA.

**Elevated Anion Gap Metabolic Acidosis**

Metabolic acidosis with an increased SAG commonly results from increased endogenous organic acid production. In lactic acidosis, lactic acid accumulates as a by-product of anaerobic metabolism. Accumulation of the ketoacids β-hydroxybutyric acid and acetoacetic acid defines the ketoacidosis of uncontrolled diabetes mellitus, alcohol intoxication, and starvation (see Table 61–5). In advanced renal failure, accumulation of phosphate, sulfate, and organic anions is responsible for the increased SAG, which is usually less than 24 mEq/L (24 mmol/L). The severe metabolic acidosis seen in myoglobinuric acute renal failure caused by rhabdomyolysis may be caused by the metabolism of large amounts of sulfur-containing amino acids released from myoglobin.

The presence of mild elevations in the SAG cannot be automatically attributed to the presence of a high SAG metabolic acidosis. Elevations in the SAG are commonly seen in hospitalized patients, especially those who are critically ill. A variety of factors can contribute to this nonspecific elevation in the SAG, including the presence of alkalosis, which increases the anionic charge of albumin and other plasma proteins. The usefulness of the SAG as a marker of acid–base status is dependent on proper interpretation of a patient’s clinical status. Despite these limitations, when the SAG exceeds 20 to 25 mEq/L (20–25 mmol/L) a significant organic acidosis is likely to be present.

High anion gap metabolic acidosis can develop in many clinical settings, including uncontrolled diabetes mellitus (see Chapter 83), alcohol intoxication (see Chapters 44 and 75), and starvation (see Chapter 72). Toxic ingestions of methanol and ethylene glycol, are also associated with high anion gap metabolic acidosis and can be differentiated from other causes of SAG because of the presence of an elevated osmolar gap. The mechanisms responsible for the development of acidosis in these settings are diverse. (See type I diabetes + ketoacidosis case in Casebook.)

**Lactic Acidosis**

Lactic acidosis is one of the most common causes of high SAG metabolic acidosis and can impact approximately 1% of hospitalized patients. Lactic acid is the end product of anaerobic metabolism of glucose (glycolysis). In normal individuals, lactic acid derived from pyruvate enters the circulation in small amounts and is promptly removed by the liver. In the liver, and to a lesser extent in the kidney, lactic acid is reoxidized to pyruvic acid, which is then metabolized to CO₂ and H₂O. The normal plasma lactate concentration in healthy subjects is approximately 1 mEq/L (1 mmol/L). The diagnosis of lactic acidosis should be considered in all patients with metabolic acidosis associated with an increased SAG. Lactic acidosis is considered to be present when lactate concentrations exceed 4 to 5 mEq/L (4–5 mmol/L) in an acyclic patient.

Classically, lactic acidosis has been differentiated into disorders associated with tissue hypoxia (type A lactic acidosis) and disorders associated with deranged oxidative metabolism (type B lactic acidosis), although the distinction between them is blurred (Table 61–6). The etiologies of lactic acidosis can also be categorized on the basis of changes in lactate production and/or utilization. Metabolic disturbances can result in increased tissue pyruvate production or impaired utilization, with proportional increases in lactate concentrations. Increased lactate production is more commonly associated with alterations in tissue redox state, resulting in preferential conversion of pyruvate to lactate. During anaerobic metabolism, reduced nicotinamide adenine dinucleotide accumulates, driving the conversion of pyruvate to lactate and increasing the lactate:pyruvate ratio. States of enhanced metabolic activity (e.g., grand mal seizures, strenuous exercise, or hyperthermia), decreased tissue oxygen delivery (e.g., severe anemia, hypoxia, circulatory shock, or carbon monoxide poisoning) or impaired oxygen utilization (e.g., cyanide toxicity) are all associated with lactic acidosis. Impaired hepatic clearance of lactate, as seen in hypoperfusion states, liver failure, and alcohol intoxication, can also result in lactic acidosis.

Cardiovascular and septic shock, with resultant tissue hypoperfusion, are the most common causes of lactic acidosis. Poor tissue perfusion and hypoxia influence enzymatic pyruvate and lactate metabolism to stimulate anaerobic glycolysis and to decrease lactate utilization. This leads to hyperlactatemia and lactic acidosis. The mortality rate of this type of lactic acidosis can be as high as 80% and correlates with the degree of hyperlactatemia.

Lactic acidosis associated with liver disease, toxins, and congenital enzyme deficiency can be caused by deranged oxidative metabolism or impaired lactate clearance. The exact role of diabetes mellitus...

in the induction of lactic acidosis is not clear. It may involve a decrease in pyruvate dehydrogenase activity, the enzyme responsible for pyruvate metabolism. Lactic acidosis in neoplastic disease is uncommon and reported mostly in patients with myeloproliferative disorders. Leukocytes and neoplastic cells in general have high rates of glycolysis. In the case of a large tumor or tightly packed bone marrow, oxygenation can be decreased, favoring the accumulation of lactate. Lactic acidosis has been reported in patients with massive liver tumors, and it has been postulated that the liver uptake of lactate is decreased in these patients. Lactic acidosis associated with seizures is usually transient and occurs because of excessive muscle activity.  

A number of medications can cause lactic acidosis.  

Two of the most common medications associated with the development of lactic acidosis are nucleoside-analog reverse transcriptase inhibitors (NRTIs) (3.9 cases per 1,000 person-years) and metformin (0.03 cases per 1,000 person-years).  

The proposed mechanism of NRTI-induced lactic acidosis is the inhibition of the enzyme DNA polymerase gamma that is responsible for mitochondrial DNA synthesis. Disruption of this enzyme can inhibit the transport of lactate into the mitochondria, leading to an accumulation in the cytoplasm. Stavudine is the NRTI most frequently associated with lactic acidosis; however, the combination of stavudine and didanosine confers the highest risk.  

The primary suspected mechanism for metformin-induced lactic acidosis is inhibition of liver gluconeogenesis as the result of its inhibitory effects on pyruvate carboxylase which is necessary for the conversion of pyruvate to glucose. Other possible pathways for metformin-associated lactic acidosis include a decrease in both hepatic intracellular pH and cardiac output and an increase in lactate production in the gut and increased renal loss of bicarbonate.  

Risk factors for metformin-induced lactic acidosis include renal insufficiency, liver disease, dehydration, advanced age, alcohol consumption, and supratherapeutic dosing. Metformin should be discontinued during periods of tissue hypoxia (e.g., myocardial infarction, sepsis), for 3 days after contrast media has been administered or 2 days before general anesthesia administration. In the latter two cases, metformin should only be reinitiated when the patient’s renal function is stable.  

Propylene glycol is commonly used as a solubilizing agent in intravenous drug preparations (e.g., lorazepam, pentobarbital) and is predominantly metabolized to lactic acid via the hepatic enzyme alcohol dehydrogenase. The administration of large doses of propylene glycol, particularly to patients with renal or liver insufficiency, can lead to a lactic acidosis with an osmolar gap and thus serial measurement of the osmolar gap can be used to detect propylene glycol accumulation.  

Reports of the association between propofol and lactic acidosis were initially described in children. This association is now recognized in adults and has come to be known as the propofol-related infusion syndrome. In addition to lactic acidosis, cardiac failure, rhabdomyolysis, and renal failure have been observed primarily because of uncoupling of oxidative phosphorylation and impaired oxidation of free fatty acids. This syndrome is most frequently seen in patients receiving propofol at high doses (>5 mg/kg/h) for more than 2 days.

**CLINICAL PRESENTATION**

Chronic metabolic acidosis is usually not associated with severe acidemia and is relatively asymptomatic. The major manifestations are in the bones, where chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteoporosis in adults. In infants and children, chronic metabolic acidosis is associated with growth failure and short stature and can be associated with nonspecific symptoms including anorexia, nausea, weight loss, and muscle weakness.  

Severe metabolic acidosis is usually associated with acute processes. The manifestations of severe acidemia (pH <7.20) involve the cardiovascular, respiratory, and central nervous systems. Hyperventilation is often the first sign of metabolic acidosis. At a pH of 7.2, pulmonary ventilation increases approximately fourfold, and an eightfold increase has been noted at a pH of 7.25. Respiratory compensation can occur as Kussmaul respirations—the deep, rapid respirations seen commonly in patients with diabetic ketoacidosis. In extremely severe acidosis (pH <6.8), CNS function is disrupted to such a degree that the respiratory center is depressed.  

CNS depression correlates more closely with spinal fluid pH than with blood pH. For this reason, neurologic symptoms tend to occur more frequently and to a greater degree in patients with respiratory acidosis because the CO2 accumulated in the respiratory form readily crosses the blood-brain barrier to cause acidosis in the CNS. Because of the slow penetration of administered bicarbonate into the CNS, the CNS pH fails to normalize as rapidly as blood pH. Therefore patients continue to hyperventilate because of sustained CNS acidity, and severe respiratory alkalosis can occur. Sustained lowering of the PaCO2 within 12 to 36 hours is to be anticipated during the correction of any metabolic acidosis.  

Systemic acidosis can cause peripheral arteriolar dilatation, characterized by flushing, a rapid heart rate, and wide pulse pressure. Initially, cardiac output can be increased, but as acidosis becomes more severe, myocardial contractility becomes impaired, and cardiac output decreases. The effects of vagal stimulation are also enhanced at pH levels lower than 7.1, probably as a consequence of inhibition of acetylcholinesterase. This increases the danger of vagally mediated bradycardia and heart block during acidosis.  

Gastrointestinal symptoms of metabolic acidosis include loss of appetite, nausea, and vomiting. Severe acidosis (pH <7.1) interferes with carbohydrate metabolism and insulin utilization, and results in hyperglycemia. Metabolic acidosis alters potassium homeostasis and contributes to the development of hyperkalemia. The magnitude of the effect on serum potassium depends on the type of acidosis: Acidosis caused by mineral acids (e.g., hydrochloric acid) are associated with a greater change in potassium levels than acidosis caused by organic acids (e.g., lactic acidosis), in which the increase in potassium attributable to the acidosis per se is minimal.

**CLINICAL PRESENTATION OF METABOLIC ACIDOSIS**

**General**  

- The patient is usually relatively asymptomatic if the acidosis is acute and mild. In those with severe acidemia (pH <7.15–7.20) the cardiovascular, respiratory, and central nervous systems can be affected.

**Symptoms**  

- The patient may complain of loss of appetite, nausea, and vomiting.

**Signs**  

- Cardiac: Flushing, a rapid heart rate, wide pulse pressure, and an increase in cardiac output can be seen initially. This can be
followed by a reduction in cardiac output, blood pressure, and liver and kidney blood flow.

- Cerebral: Obtundation or coma.
- Metabolic: Insulin resistance; increased protein degradation; increased metabolic demands.
- Gastrointestinal: Nausea, vomiting, loss of appetite.
- Respiratory: Dyspnea, hyperventilation with deep, rapid respiration is seen in those with severe acidosis.
- Chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteoporosis in adults.

Laboratory Tests

- Serum CO₂ is low. Hyperglycemia and hyperkalemia are common. Patients with a pH <7.2 are deemed to have a severe acidosis.

### COMPENSATION

The patient’s primary means to compensate for metabolic acidosis is to increase carbon dioxide excretion by increasing respiratory rate. This results in a decrease in PaCO₂. This ventilatory acidosis is to increase carbon dioxide excretion by increasing respiratory rate. The plasma [HCO₃⁻] should decrease by 1.3 times the fall in plasma [HCO₃⁻] (in mEq/L)

\[ \text{LD(mEq or mmol/L)} = (0.5 \times \text{BW}) \times \left( \text{desired [HCO₃⁻]} - \text{current [HCO₃⁻]} \right) \]

For a 60-kg patient with a serum bicarbonate of 15 mEq/L (24–15 mmol/L), the loading dose is calculated thus:

\[ \text{LD(mEq)} = (0.5 \times 60 \times 60) \times (24 \text{ mEq/L} - 15 \text{ mEq/L}) = 30 \times 9 \text{ mEq/L} = 270 \text{ mEq/L} \]

The anticipated PaCO₂, associated with a given bicarbonate concentration for patients with uncomplicated metabolic acidosis can be calculated as:

\[ \text{Paco}_2 = \left(1.5 \times [\text{HCO}_3^-]\right) + 8 \pm 2 \text{ for PaCO}_2 \text{ in mm Hg} \]

\[ \text{Paco}_2 = \left(0.2 \times [\text{HCO}_3^-]\right) + 1.1 \pm 0.3 \text{ for PaCO}_2 \text{ in kPa} \]

For example, 95% of patients with a plasma bicarbonate of 16 mEq/L (16 mmol/L) should have an arterial PaCO₂ of 30 to 34 mm Hg (4.0–4.6 kPa). An observed arterial PaCO₂ within this range is consistent with physiologic respiratory compensation for a metabolic acidosis and suggests that there is no respiratory disturbance. In contrast, if the PaCO₂ is less than 30 mm Hg (4.0 kPa), a superimposed respiratory alkalosis can be present, whereas if the PaCO₂ is greater than 34 mm Hg (4.6 kPa), a superimposed respiratory acidosis is likely present.

### TREATMENT

#### Metabolic Acidosis

- **CHRONIC METABOLIC ACIDOSIS**

  Asymptomatic patients with mild to moderate degrees of acidemia (plasma bicarbonate of 12 to 20 mEq/L (12–20 mmol/L); pH 7.2–7.4) do not require emergent therapy. They can usually be managed with gradual correction of the acidemia, over a period of days to weeks, using oral sodium bicarbonate or other alkali preparations (Table 61–8). In all forms of chronic metabolic acidosis, primary therapy should be directed at treating the underlying disease state. Gastrointestinal pathology should be treated to reduce ongoing bicarbonate losses, and factors that exacerbate RTA should be treated. If acidemia persists, alkali therapy should be instituted with the goal of normalization of blood pH. The loading dose (LD) of alkali to initially correct the acidemia can be calculated as follows where \( V_d \) is the volume of distribution of bicarbonate:

\[ \text{LD(mEq or mmol/L)} = (V_d \times \text{HCO}_3^- \text{ body weight [BW]}) \times (\text{desired [HCO}_3^-] - \text{current [HCO}_3^-]) \]

For a 60-kg patient with a serum bicarbonate of 15 mEq/L (24–15 mmol/L), the loading dose is calculated thus:

\[ \text{LD(mEq)} = (0.5 \times 60 \times 60) \times (24 \text{ mEq/L} - 15 \text{ mEq/L}) = 30 \times 9 \text{ mEq/L} = 270 \text{ mEq/L} \]

The calculated loading dose of alkali should be administered over several days to avoid volume overload from the accompanying sodium load. For this scenario, a regimen of 60 to 70 mEq (60–70 mmol) three times a day for 3 to 5 days should result in an increase in HCO₃⁻ levels toward normal. In addition to the calculated loading dose, supplemental alkali must also be provided to replace ongoing losses, which can be approximated to be 2 mEq/kg (2 mmol/kg) per day or 40 mEq (40 mmol) 3 times a day. In patients with associated volume depletion, bicarbonate replacement can be provided simultaneously with volume resuscitation by substituting bicarbonate for chloride in intravenous crystalloid solutions.

In patients with chronic metabolic acidosis because of gastrointestinal bicarbonate losses, maintenance therapy should provide sufficient alkali to replace ongoing bicarbonate losses. The magnitude of this replacement is variable and can be substantial (>10 mEq/kg [>10 mmol/kg] per day). In addition, associated losses of other electrolytes, such as potassium and magnesium, may need to be replaced (see Chapter 60).
Proximal (type II) RTA is a bicarbonate-wasting disorder that requires the administration of large maintenance doses of alkali (10–15 mEq/kg [10–15 mmol/kg] per day). As alkali replacement raises the serum bicarbonate concentration toward normal, the proximal tubule’s capacity to reabsorb bicarbonate is overwhelmed, and renal bicarbonate wasting increases. In children, aggressive therapy of proximal RTA is necessary to avoid growth retardation and osteopenia. Because this is generally a mild, nonprogressive acidosis in adults, the benefit of alkali therapy is frequently outweighed by the risks of increased potassium wasting. In patients with classic distal (type I) RTA, maintenance therapy usually requires only enough alkali to buffer the amount of acid generated from dietary intake and metabolism. This usually approximates 1 to 3 mEq/kg per day (1–3 mmol/kg).

After initial potassium deficits are replaced, ongoing potassium supplementation may not be required, as renal potassium losses decrease following initiation of appropriate alkali therapy. The use of potassium alkali salts can, however, be desirable in patients with associated nephrolithiasis, because sodium salts can increase urinary calcium excretion.

The metabolic acidosis associated with hyperkalemic distal (type IV) RTA with hyperreninemic-hypoaldosteronemia that is often seen in patients with diabetes mellitus can be corrected by the administration of supplemental alkali (1–2 mEq/kg [1–2 mmol/kg] per day). Despite the risk of increased potassium wasting, potassium alkali salts can be desirable in patients with associated nephrolithiasis, because sodium salts can increase urinary calcium excretion.

The metabolic acidosis associated with hyperkalemic distal (type IV) RTA with hyperreninemic-hypoaldosteronemia that is often seen in patients with diabetes mellitus can be corrected by the administration of supplemental alkali (1–2 mEq/kg [1–2 mmol/kg] per day). Despite the risk of increased potassium wasting, potassium alkali salts can be desirable in patients with associated nephrolithiasis, because sodium salts can increase urinary calcium excretion.

SODIUM BICARBONATE

While sodium bicarbonate administration provides fluid and electrolyte replacement and increases arterial pH, neither animal nor human data support the use of sodium bicarbonate to treat metabolic acidosis.
clinical studies demonstrate an improvement in cardiac function, organ perfusion, or intracellular pH. In addition, sodium bicarbonate administration can actually have paradoxical adverse effects on intracellular pH. When bicarbonate is given by IV infusion, the carbon dioxide generated diffuses more readily than bicarbonate across cell membranes and into cerebrospinal fluid. Therefore, the intracellular pH can actually be decreased by administration of bicarbonate.  

**CLINICAL CONTROVERSY**

Although it has been recommended that sodium bicarbonate be administered to raise the arterial pH to approximately 7.20, there are no controlled clinical trials demonstrating that sodium bicarbonate administration is significantly better than general supportive care in reducing morbidity and mortality in these patients.  

Excessive sodium bicarbonate administration can result in (1) a shift of the oxyhemoglobin saturation curve to the left thereby impairing oxygen release from hemoglobin to tissues; (2) sodium and water overload, with subsequent pulmonary congestion and hyponatremia; (3) paradoxical tissue acidosis as a result of the production of CO$_2$ that freely diffuses into myocardial and cerebral cells; and (4) decreased ionized calcium with a resultant decrease in myocardial contractility. If there is an endogenous source of bicarbonate, such as can occur in the case of ketoacidosis or lactic acidosis, a bicarbonate “overshoot” can develop because the ketoacids (acetoacetic acid and β-hydroxybutyric acid) or lactic acid are converted in the liver to bicarbonate once the underlying cause of acidosis is corrected. Alkalosis can also result if too much sodium bicarbonate is administered too quickly.  

If intravenous sodium bicarbonate is used, one must be mindful that the goals are to increase, not normalize, pH (to approximately 7.20) and plasma bicarbonate (to 8–10 mEq/L [8–10 mmol/L]). There is no calculative method that will assure attainment of these goals with a given dose of sodium bicarbonate because of the multiplicity of competing processes that can affect acid–base status (e.g., vomiting, potential increases in endogenous acid production, and renal failure) and the marked variability in the volume of distribution of bicarbonate (50% of body weight in patients with mild acidosis to approximately 100% in those with severe acidosis). Adrogue and Madias recommended that the dose of sodium bicarbonate be calculated using a distribution volume of 50% of body weight for all patients to avoid overtreatment. The total dose calculated as described previously in the RTA section should be administered as an infusion over one-half to several hours. Follow-up monitoring of arterial blood gases, beginning no sooner than 30 minutes after the end of the infusion, should be used to guide further therapeutic decisions.  

Bicarbonate therapy is generally not necessary for patients with cardiac arrest, even if the initial arrest was unmonitored. The American Heart Association’s Advanced Cardiac Life Support (ACLS) provider manual states that sodium bicarbonate is not useful or effective during resuscitation in hypoxic patients with lactic acidosis. Additionally, sodium bicarbonate is considered to be not useful or effective in those who are undergoing prolonged resuscitation with effective ventilation. Furthermore, if sodium bicarbonate is used, it should be used only after defibrillation, cardiac compression, support of ventilation including intubation, and drug therapies such as epinephrine and antiarrhythmic agents have been employed. The initial dose of sodium bicarbonate in this situation is 1 mEq/kg (1 mmol/kg) administered by rapid, direct intravenous injection. Subsequent doses of sodium bicarbonate should be based on measurements of arterial blood pH and PaCO$_2$ given the propensity for it to cause alkalemia.  

### TROMETHAMINE  

THAM, available as a 0.3 N solution, is a highly alkaline, sodium-free organic amine that acts as a proton acceptor to prevent or correct acidosis. THAM combines with hydrogen ions from carbonic acid to form bicarbonate and a cationic buffer. THAM also acts as an osmotic diuretic to increase urine flow, urine pH, and the excretion of fixed acids, CO$_2$, and electrolytes. At pH 7.4, 30% of THAM is not ionized and therefore can penetrate into cells and neutralize acidic anions of the intracellular fluid. Intracellular pH increases have been noted within 1 hour after the infusion of THAM. There is, however, no clinical or physiologic evidence that this action is beneficial, or that THAM is more efficacious than sodium bicarbonate. When THAM is used, it must be administered slowly, with careful monitoring to avoid alkalosis. The usual empiric dosage range for tromethamine is 1 to 5 mmol/kg administered intravenously over 1 hour, but doses up to 1.25 mmol/kg can be given over 5 to 15 minutes in acute situations. The dose of THAM can be individualized using the following equation:

Dose of THAM (in mL) = 1.1 × BW (in kilograms) × base deficit where base deficit = normal [HCO$_3^-$] minus current [HCO$_3^-$].  

The need for additional THAM is determined by serial measurements of the serum bicarbonate concentration and calculation of the base deficit. Large doses can cause respiratory depression as a result of an increase in blood pH and a decrease in PaCO$_2$ concentration. THAM solution is highly alkaline and can cause severe inflammation, vascular spasm, or tissue damage (necrosis, sloughing, pain, chemical phlebitis, or thrombosis) if infiltration occurs. Hyperkalemia, hypoglycemia, hypocalemia, and impaired coagulation have also been reported. This agent should only be used with extreme caution in patients with severe liver or kidney failure.  

### CARBICARB  

Carbicarb is an equimolar mixture of sodium carbonate (Na$_2$CO$_3$) and sodium bicarbonate (NaHCO$_3$). Given that the carbonate ion is a stronger base than bicarbonate, Carbicarb preferentially buffers hydrogen ions resulting in the formation of bicarbonate rather than CO$_2$. Thus Carbicarb limits, but does not eliminate, the generation of CO$_2$. Unlike bicarbonate, which can produce a paradoxical intracellular acidosis and thereby impair cardiac function, Carbicarb appears to correct intracellular acidosis if present. Despite these effects, there are no consistent data on the effects of carbicarb on hemodynamic endpoints and this agent is not available for use in humans.  

### DICHLOROACETATE  

Dichloroacetate (DCA), another investigational agent, facilitates aerobic lactate metabolism by stimulating the activity of lactate dehydrogenase, thus reversing hyperlactatemia and elevating blood pH. DCA, when compared to conventional management in controlled studies, however, has not been shown to improve hemodynamic parameters or clinical outcomes. DCA can cause mild drowsiness and peripheral neuropathy that can be ameliorated or prevented with thiamine supplementation. The future role of DCA in the management of metabolic acidosis, particularly lactic acidosis, remains to be clarified.
Pathophysiology

Metabolic alkalosis is a simple acid–base disorder that presents as alkalocemia (increased arterial pH) with an increase in plasma bicarbonate. It is an extremely common entity in hospitalized patients with acid–base disturbances. Under normal circumstances, the kidney is readily able to excrete an alkali load. Thus evaluation of patients with metabolic alkalosis must consider two separate issues: (1) the initial process that generates the metabolic alkalosis; and (2) alterations in renal function that maintain the alkalemic state.  

The generation of metabolic alkalosis can also result from excessive losses of hydrogen ion from the kidneys or stomach or from a gain secondary to the ingestion or administration of bicarbonate-rich fluids. Gastric juice, rich in chloride and hydrogen ion, is secreted at a rate of less than 50 mL/h in the basal state, but can increase up to five-fold with stimulation. In the gastric parietal cells, hydrogen ion and bicarbonate are generated from CO₂ and water. The hydrogen ion is secreted into gastric fluid, and the bicarbonate is retained in the ECF. Normally, an amount of bicarbonate equal to the bicarbonate generated in the stomach is eliminated in the alkaline pancreatic and small-bowel secretions, maintaining hydrogen ion balance. With vomiting and nasogastric suctioning, hydrogen ion is lost externally and metabolic alkalosis results. Diarrhea, as seen with secretory villous adenomas and other secretory diarrheas, often results in excessive gastrointestinal losses of chloride-rich, bicarbonate-poor fluid and thus leads to the generation of metabolic alkalosis.  

Diuretic agents acting on the thick ascending limb of the loop of Henle (e.g., furosemide, bumetanide, and torsemide) and distal convoluted tubule (e.g., thiazides), have most commonly been associated with the generation of metabolic alkalosis. These agents promote the excretion of sodium and potassium almost exclusively in association with chloride, without a proportionate increase in bicarbonate excretion. Collecting duct hydrogen ion secretion is stimulated directly by the increased luminal flow rate and sodium delivery, and indirectly by intravascular volume contraction, which results in secondary hyperaldosteronism. Renal ammoniagenesis can also be stimulated by concomitant hypokalemia, further augmenting net acid excretion.  

Increased renal acid excretion can also be the result of excess mineralocorticoid activity. Elevated mineralocorticoid levels directly stimulate collecting duct hydrogen ion secretion and indirectly increase ammoniagenesis by causing hypokalemia. Increased mineralocorticoid activity can result from Cushing syndrome, primary hyperaldosteronism, or hyperaldosteronism secondary to increased renin activity (e.g., malignant hypertension). In Bartter and Gitelman syndromes, defects in sodium transport in the loop of Henle (Bartter) or distal convoluted tubule (Gitelman) lead to hypokalemia, secondary hyperaldosteronism, and metabolic alkalosis. In Liddle’s syndrome, enhanced sodium reabsorption by the cortical collecting duct epithelial sodium channel results in a syndrome of pseudo-hyperaldosteronism. Administration of high doses of penicillins (e.g., ticarcillin) can produce metabolic alkalosis because they act as nonreabsorbable anions. High concentrations of poorly reabsorbable anions in the distal renal tubule increase luminal flow rate and luminal electronegativity, which enhances the secretion of potassium and hydrogen ion and results in hypokalemia and metabolic alkalosis.  

Metabolic alkalosis can also be generated by the gain of exogenous alkali. This can be seen as a result of bicarbonate administration or from the infusion of organic anions that are metabolized to bicarbonate, such as acetate, lactate, and citrate. The milk-alkali syndrome was historically a common cause of metabolic alkalosis in patients with peptic ulcer disease secondary to the ingestion of large quantities of milk products and antacids. With the advent of alternative therapies for dyspeptic syndromes that are far more effective than milk, this syndrome is now rarely seen.

**TABLE 61-10** Causes of Metabolic Alkalosis Differentiated on the Basis of Their Responsiveness to Sodium Chloride

Metabolic alkalosis is predominantly maintained because of an abnormality in renal function. Normally, the kidneys are capable of excreting all of the excess bicarbonate presented to them, even during periods of increased bicarbonate loads. As the serum bicarbonate concentration increases, the filtered bicarbonate load exceeds the maximal rate for bicarbonate reabsorption, and the excess bicarbonate is excreted in the urine. Under normal circumstances, the excess bicarbonate is rapidly excreted, and metabolic alkalosis does not occur or is corrected in a matter of hours. Several mechanisms can impair renal bicarbonate excretion and contribute to the maintenance phase of metabolic alkalosis. In general, these mechanisms can be divided into volume-mediated processes (sodium chloride–responsive) and volume-independent processes (sodium chloride–resistant) that are predominantly associated with excess mineralocorticoid activity and hypokalemia (Table 61–10). Intravascular volume depletion maintains metabolic alkalosis through a number of mechanisms. Decreases in the glomerular filtration rate reduce the filtered load of bicarbonate at any given serum concentration, thereby decreasing the kidney’s ability to excrete a bicarbonate load. Although this can play a role in patients with chronic kidney disease, it is also an important factor in patients in whom intravascular volume contraction accompanies metabolic alkalosis. Decreased effective arterial blood volume also enhances proximal and distal tubular sodium reabsorption. Sodium reabsorption must be coupled with reabsorption of an anion, such as chloride or bicarbonate, or exchange with a cation, such as potassium or hydrogen, to maintain charge neutrality. In the proximal tubule, increased sodium reabsorption stimulates bicarbonate reabsorption. In the distal nephron, increased sodium reabsorption, particularly in the setting of hypokalemia, stimulates hydrogen ion secretion. Mineralocorticoid excess also plays a significant role in the maintenance of metabolic alkalosis. In patients with volume-responsive...
metabolic alkalosis, intravascular volume depletion stimulates aldosterone secretion. As discussed earlier, excess mineralocorticoid activity can also underlie the generation of metabolic alkalosis. In either situation, the increased mineralocorticoid effect stimulates collecting duct hydrogen ion secretion. Metabolic alkalosis can also be maintained by persistent hypokalemia, enhancing proximal tubular bicarbonate reabsorption, stimulating ammoniagenesis, and increasing distal tubular hydrogen ion secretion.47

**Clinical Presentation**

There are no unique signs or symptoms associated with mild to moderate metabolic alkalosis, but patients may complain of symptoms related to the underlying cause of the disorder (e.g., muscle weakness with hypokalemia or postural dizziness with volume depletion). They may have a history of vomiting, gastric drainage, or diuretic use, all of which contribute to the development of metabolic alkalosis. Severe alkalosis (blood pH >7.60) has been associated with cardiac arrhythmias, particularly in patients with heart disease, hyperventilation, and hypoxemia.48 Neuromuscular irritability can be present, with signs of tetany or hyperactive reflexes, possibly caused by the decreased ionized calcium concentration that occurs secondary to the increase in pH. This decrease in ionized calcium may be caused by a conformational change in the albumin molecules to which the calcium is bound, resulting in increased binding, or by decreased competition from hydrogen ions for binding sites on the albumin molecule. Mental confusion, muscle cramping, and paresthesia can also occur. Lastly, patients will be more difficult to liberate from mechanical ventilation. (Please see metabolic alkalosis case 59 from Casebook.)

**Compensation**

The respiratory response to metabolic alkalosis is hypoventilation, which results in an increased PaCO₂. Respiratory compensation is initiated within hours when the central and peripheral chemoreceptors sense an increase in pH. The PaCO₂ increases 6 to 7 mm Hg (0.8–0.9 kPa) for each 10-mEq/L (10 mmol/L) increase in bicarbonate, up to a PaCO₂ of approximately 50 to 60 mm Hg (6.7–8.0 kPa) (see Table 61–7) before hypoxia sensors react to prevent further hypoventilation. If the PaCO₂ is normal or less than normal, one should consider the presence of a superimposed respiratory alkalosis, which can be secondary to fever, gram-negative sepsis, or pain.

**TREATMENT**

### Metabolic Alkalosis

Because the body tolerates alkalemia far less well than acidemia, treatment of metabolic alkalosis is nearly always required and should be aimed at correcting the factor(s) responsible for the maintenance of the alkalosis.23,49 For example, vomiting should be treated with antiemetics, gastric losses of hydrogen ion during nasogastric suction can be modulated by giving histamine blockers such as ranitidine or proton pump inhibitors such as omeprazole, and reducing or discontinuing diuretic therapy.47,50 Metabolic alkalosis will persist until the renal mechanism responsible for maintaining the disorder is corrected, despite the fact that the original cause of the elevated plasma bicarbonate may have resolved. For example, hypovolemia should be treated with sodium chloride (i.e., diuretic abuse or nasogastric suction) to allow excretion of bicarbonate by the kidney. However, patients with severely compromised cardiovascular function may not be able to tolerate this therapeutic approach. In situations such as this and/or the presence of life-threatening alkalosis, some have advocated reduction in pH by control of ventilation.4 Although controlled hypoventilation, sometimes using inspired CO₂ with supplemental oxygen to prevent hypoxia can be life-saving,4 this approach is not universally accepted.51 Therapy for metabolic alkalosis can be conceptualized on the basis of the sodium chloride responsiveness of the disorders as shown in Figure 61–4.
SODIUM CHLORIDE–RESPONSIVE DISORDERS

Sodium chloride–responsive disorders usually result from volume depletion and chloride loss, which can accompany severe vomiting, prolonged nasogastric suction, and diuretic therapy. Initially, therapy is directed at expanding intravascular volume and replenishing chloride stores. Sodium and potassium chloride–containing solutions should be administered to patients who can tolerate the volume load.47,49 Patients with metabolic alkalosis who are volume overloaded or intolerant to volume administration because of congestive heart failure can benefit from the carboxyhydrate inhibitor acetazolamide. This agent inhibits the action of carboxyhydrate anhydride, thereby inhibiting renal bicarbonate reabsorption. Unfortunately, it also increases the renal losses of potassium and phosphate. Administration of acetazolamide (250–375 mg once or twice daily) can promote a sufficient bicarbonate diuresis and return the pH toward normal.53 However, because the clinical effectiveness of the drug declines as the HCO₃⁻ concentration decreases, only rarely will this approach fully correct the alkalosis.47

Acidifying agents including hydrochloric acid, ammonium chloride, and arginine monohydrochloride can be used to treat severe (pH >7.6) symptomatic metabolic alkalosis.52 In general, this management is reserved for patients who are unresponsive to conventional fluid and electrolyte management or who are unable to tolerate the requisite volume load because of decompensated congestive heart failure or advanced renal failure.52 Alternatively, hemodialysis using a low-bicarbonate dialysate can be used for the rapid correction of metabolic alkalosis.

HYDROCHLORIC ACID

Hydrochloric acid is usually infused intravenously via a large central vein as a 0.1 to 0.25 N HCl solution in either 5% dextrose or normal saline, although sterile water has also been used. Extemporaneously prepared solutions can be made by adding 100 to 250 mEq (100–250 mmol) of HCl through a 0.22-mm filter into a glass container prepared solutions can be made by adding 100 to 250 mEq (100–250 mmol) of HCl through a 0.22-mm filter into a glass container. Hydrochloric acid can also be added to parenteral nutrient solutions and administered via a central line without serious degradation of proteins.53 The rate of infusion should be 100 to 125 mL/h (10–25 mEq/h [10–25 mmol/h]), with frequent monitoring of arterial blood gases. To prevent overcorrection, the infusion should be stopped when the arterial pH decreases to 7.50.46 The dose of hydrochloric acid can be based on an estimate of the total body chloride deficit:46

\[
\text{Dose HCl (in mEq or mmol)} = \left[0.2 \text{ L/kg} \times \text{BW (in kilograms)}\right] \\
\times [103 – \text{observed serum chloride}]
\]

where the estimated chloride space is 0.2 times the body weight, and the average serum chloride is 103 mEq/L (103 mmol/L). Alternatively, the dose can be calculated based on the estimated base deficit:46

\[
\text{Dose HCl (in mEq or mmol)} = \left[0.5 \text{ L/kg} \times \text{BW (in kilograms)}\right] \\
\times (\text{desired}[\text{HCO}_3^-] – \text{observed}[\text{HCO}_3^-])
\]

The dose of hydrochloric acid is usually infused intravenously over 12 to 24 hours.44 A severe transient respiratory acidosis can occur if the hydrochloric acid is infused too quickly because of a slower reduction of the elevated bicarbonate concentration in the cerebrospinal fluid than in the extracellular fluid. Improvement is usually seen within 24 hours of initiating therapy. Arterial blood gases and serum electrolytes should be drawn every 4 to 8 hours to evaluate and adjust therapy.

AMMONIUM CHLORIDE

Ammonium chloride has a limited role in the treatment of metabolic alkalosis. The liver converts ammonium chloride (NH₄Cl) to urea and free hydrochloric acid:46

\[2\text{NH}_4\text{Cl} + 2\text{HCO}_3^- \rightarrow \text{CO(NH}_2\text{)}_2 + \text{CO}_2 + 3\text{H}_2\text{O} + 2\text{Cl}^-\]

The dose of ammonium chloride can be calculated on the basis of the chloride deficit using the same method as for HCl and assuming that 20 g ammonium chloride will provide 374 mEq (374 mmol) of H⁺. However, only one half of the calculated dose of ammonium chloride should be administered so as to avoid ammonia toxicity. Ammonium chloride is available as a 26.75% solution containing 100 mEq (100 mmol) of H⁺ in 20 mL, which should be further diluted prior to administration. A dilute solution can be prepared by adding 20 mL of ammonium chloride to 500 mL of normal saline and infusing the solution at a rate of no more than 1 mEq/min (1 mmol/min). Improvement in metabolic status is usually seen within 24 hours. CNS toxicity, marked by confusion, irritability, seizures, and coma, has been associated with more rapid rates of administration. Ammonium chloride must be administered cautiously to patients with renal or hepatic impairment. In patients with hepatic dysfunction, impaired conversion of ammonia to urea can result in increased ammonia levels and worsened encephalopathy. In patients with renal failure, the increased urea synthesis can exacerbate uremic symptoms.36

ARGININE MONOHYDROCHLORIDE

Arginine monohydrochloride at a dose of 10 g/h given intravenously has been used to treat metabolic alkalosis, although it was never FDA approved for this purpose.44 Like ammonium chloride, arginine must undergo metabolism by the liver to produce hydrogen ions, with a conversion of 100 g to 475 mEq (475 mmol) of H⁺. Unlike ammonium chloride, arginine combines with ammonia in the body to synthesize urea; thus it can be used in patients with relative hepatic insufficiency. Patients with renal insufficiency should not receive arginine monohydrochloride because it can significantly elevate blood urea nitrogen and is associated with severe hyperkalemia.46,47 The increase in potassium is caused by arginine-induced shifts of potassium from the intracellular to the extracellular space.

SODIUM CHLORIDE–RESISTANT DISORDERS

Management of these disorders usually consists of treatment of the underlying cause of the mineralocorticoid excess. For patients taking a corticosteroid, a dosage reduction or a switch to a corticosteroid with less mineralocorticoid activity (e.g., methylprednisolone) should be considered. Patients with an endogenous source of excess mineralocorticoid activity can require surgery or the administration of spironolactone, amiloride, or triamterene.47,49,55

Spironolactone is a competitive antagonist of the mineralocorticoid receptor. Amiloride and triamterene are potassium-sparing diuretics that inhibit the epithelial sodium channel in the distal...
convoluted tubule and collecting duct. All three agents inhibit aldosterone-stimulated sodium reabsorption in the collecting duct. In addition, spironolactone directly inhibits aldosterone stimulation of the hydrogen ion secretory pump. Thus, most patients with mineralocorticoid excess, including Barter and Gitelman syndromes, respond to therapy with these agents.55–57 Liddle syndrome, which is a form of pseudohypoaldosteronism caused by overactivity of the epithelial sodium channel, is not responsive to spironolactone but can be treated with either amiloride or triamterene. Although experience is limited, some patients with Barter and Gitelman syndromes may respond to nonsteroidal anti-inflammatory agents or angiotensin-converting enzyme inhibitors.55–57 Finally, aggressive potassium repletion can correct the alkalosis in those who have not responded to the approaches outlined above.

**RESPIRATORY ACID–BASE DISORDERS**

As with the metabolic acid–base disturbances, there are two cardinal respiratory acid–base disturbances: respiratory acidosis and respiratory alkalosis. These disorders are generated by a primary alteration in carbon dioxide excretion, which changes the concentration of carbon dioxide, and therefore the carbonic acid concentration in body fluids. A primary reduction in $\text{Pa CO}_2$ causes an increase in $\text{pH}$ (respiratory alkalosis), and a primary increase in $\text{Pa CO}_2$ causes a decrease in $\text{pH}$ (respiratory acidosis). Unlike the metabolic disturbances, for which respiratory compensation is rapid, metabolic compensation for the respiratory disturbances is slow. Hence, these disturbances can be further divided into acute disorders, with a duration of minutes to hours, and where metabolic compensation has yet to occur, and chronic disorders that have been present long enough for metabolic compensation to be complete.

**RESPIRATORY ALKALOSIS**

Respiratory alkalosis is characterized by a primary decrease in $\text{Pa CO}_2$ that leads to an elevation in $\text{pH}$. The $\text{Pa CO}_2$ decreases when the excretion of $\text{CO}_2$ by the lungs exceeds the metabolic production of $\text{CO}_2$. It is the most frequently encountered acid–base disorder, occurring physiologically in normal pregnancy and in persons living at high altitudes.59 Respiratory alkalosis also occurs frequently among hospitalized patients (Table 61–11).

$\text{Pa CO}_2$, partial pressure of carbon dioxide from arterial blood.

### Pathophysiology

A decrease in $\text{Pa CO}_2$ occurs when ventilatory excretion exceeds metabolic production. Because endogenous production of $\text{CO}_2$ is relatively constant, negative $\text{CO}_2$ balance is primarily caused by an increase in ventilatory excretion of $\text{CO}_2$ (hyperventilation). The metabolic production of $\text{CO}_2$, however, can be increased during periods of stress or with excess carbohydrate administration (e.g., parenteral nutrition). Hyperventilation can develop from an increase in neurochemical stimulation via either central or peripheral mechanisms, or be the result of voluntary or mechanical (iatrogenic) hyperventilation.

A decrease in $\text{Pa CO}_2$ can occur in patients with cardiogenic, hypovolemic, or septic shock because oxygen delivery to the carotid and aortic chemoreceptors is reduced. This relative deficit in $\text{Pa CO}_2$ stimulates an increase in ventilation. The hyperventilation in sepsis is also mediated via a central mechanism. Hyperventilation-induced respiratory alkalosis with an elevation in cardiac index and hypotension without peripheral vasoconstriction can therefore be an early sign of sepsis.

### Clinical Presentation

Although most patients are asymptomatic, respiratory alkalosis can cause adverse neuromuscular, cardiovascular, and gastrointestinal effects.59 During periods of decreased $\text{Pa CO}_2$, there is a decrease in cerebral blood flow, which can be responsible for symptoms of light-headedness, confusion, decreased intellectual functioning, syncope, and seizures. Nausea and vomiting can occur, probably as a result of cerebral hypoxia. In severe respiratory alkalosis, cardiac arrhythmias can occur because of sensitization of the myocardium to the arrhythmogenic effects of circulating catecholamines.7 Acute respiratory alkalosis has no effect on blood pressure or cardiac output in awake individuals. Anesthetized patients, however, can experience a decrease in both cardiac output and blood pressure, possibly owing to the lack of a tachycardic response.59

The concentration of serum electrolytes can also be altered secondary to the development of respiratory alkalosis. The serum chloride concentration is usually slightly increased, and serum potassium concentration can be slightly decreased. Clinically significant hypokalemia can be a consequence of extreme respiratory alkalosis, although the effect is usually very small or negligible.2,59 Serum phosphorus concentration can decrease by as much as 1.5 to 2.0 mg/dL (0.48–0.65 mmol/L) because of the shift of inorganic phosphate into cells. Reductions in the blood ionized calcium concentration can be partially responsible for symptoms such as muscle cramps and tetany. Approximately 50% of calcium is bound to albumin, and an increase in $\text{pH}$ results in an increase in binding.24
Causes of Acute Respiratory Acidosis

Renal Disorders

reduced Pa\textsubscript{CO}\textsubscript{2} and pH on renal reabsorption of chloride and bicarbonate. The basis of the degree of renal compensation (see pH not exceeding 7.50), treatment is often not required. The first cases, have few or no symptoms and pH alterations are usually mild. Because most patients with respiratory alkalosis, especially chronic, are asymptomatic. The initial response of the body to acute respiratory alkalosis is chemical buffering: hydrogen ions are released from the body’s buffers — intracellular proteins, phosphates, and hemoglobin — and titrate down the serum bicarbonate concentration. This process occurs within minutes. Acutely, the bicarbonate concentration can be decreased by a maximum of 3 mEq/L (3 mmol/L) for each 10-mm Hg (1.3 kPa) decrease in Pa\textsubscript{CO}\textsubscript{2} (see Table 61–7). When only physicochemical buffering has occurred, the disturbance is referred to as acute respiratory alkalosis.

Metabolic compensation occurs when respiratory alkalosis persists for more than 6 to 12 hours. In response to the alkalemia, proximal tubular bicarbonate reabsorption is inhibited, and the serum bicarbonate concentration decreases. Renal compensation is usually complete within 1 to 2 days. The renal bicarbonaturia, as well as decreased NH\textsubscript{4}\textsuperscript{+} and titratable acid excretion, are direct effects of the reduced Pa\textsubscript{CO}\textsubscript{2} and pH on renal reabsorption of chloride and bicarbonate. The acuity of the respiratory alkalosis can be assessed on the basis of the degree of renal compensation (see Table 61–7). In fully compensated respiratory alkalosis, the bicarbonate concentration decreases by 4 mEq/L (4 mmol/L) below 24 for each 10-mm Hg (1.3 kPa) drop in Pa\textsubscript{CO}\textsubscript{2}. For example, a sustained decrease in Pa\textsubscript{CO}\textsubscript{2} of 20 mm Hg (2.7 kPa) will lower serum bicarbonate from 24 to 14 mEq/L (24–14 mmol/L) with a resultant pH of 7.46. Bicarbonate concentrations differing from those anticipated using the preceding guidelines suggest a mixed acid–base disorder.

**Compensation**

The initial response of the body to acute respiratory alkalosis is chemical buffering: hydrogen ions are released from the body’s buffers — intracellular proteins, phosphates, and hemoglobin — and titrate down the serum bicarbonate concentration. This process occurs within minutes. Acutely, the bicarbonate concentration can be decreased by a maximum of 3 mEq/L (3 mmol/L) for each 10-mm Hg (1.3 kPa) decrease in Pa\textsubscript{CO}\textsubscript{2} (see Table 61–7). When only physicochemical buffering has occurred, the disturbance is referred to as acute respiratory alkalosis.

Metabolic compensation occurs when respiratory alkalosis persists for more than 6 to 12 hours. In response to the alkalemia, proximal tubular bicarbonate reabsorption is inhibited, and the serum bicarbonate concentration decreases. Renal compensation is usually complete within 1 to 2 days. The renal bicarbonaturia, as well as decreased NH\textsubscript{4}\textsuperscript{+} and titratable acid excretion, are direct effects of the reduced Pa\textsubscript{CO}\textsubscript{2} and pH on renal reabsorption of chloride and bicarbonate. The acuity of the respiratory alkalosis can be assessed on the basis of the degree of renal compensation (see Table 61–7). In fully compensated respiratory alkalosis, the bicarbonate concentration decreases by 4 mEq/L (4 mmol/L) below 24 for each 10-mm Hg (1.3 kPa) drop in Pa\textsubscript{CO}\textsubscript{2}. For example, a sustained decrease in Pa\textsubscript{CO}\textsubscript{2} of 20 mm Hg (2.7 kPa) will lower serum bicarbonate from 24 to 14 mEq/L (24–14 mmol/L) with a resultant pH of 7.46. Bicarbonate concentrations differing from those anticipated using the preceding guidelines suggest a mixed acid–base disorder.

**TREATMENT**

**Respiratory Alkalosis**

Because most patients with respiratory alkalosis, especially chronic cases, have few or no symptoms and pH alterations are usually mild (pH not exceeding 7.50), treatment is often not required. The first consideration in the treatment of acute respiratory alkalosis with pH >7.50 is the identification and correction of the underlying cause. Relief of pain, correction of hypovolemia with intravenous fluids, treatment of fever or infection, treatment of salicylate overdose, and other direct measures can prove effective. A rebreathing device, such as a paper bag, can be useful in controlling hyperventilation in the Inspired carbon dioxide concentration, which should increase the carbon dioxide tension of the patient, correcting the respiratory alkalosis. In patients breathing more rapidly than the ventilator settings, sedation with or without paralysis can be employed.

**Respiratory Alkalosis**

Because most patients with respiratory alkalosis, especially chronic cases, have few or no symptoms and pH alterations are usually mild (pH not exceeding 7.50), treatment is often not required. The first consideration in the treatment of acute respiratory alkalosis with pH >7.50 is the identification and correction of the underlying cause. Relief of pain, correction of hypovolemia with intravenous fluids, treatment of fever or infection, treatment of salicylate overdose, and other direct measures can prove effective. A rebreathing device, such as a paper bag, can be useful in controlling hyperventilation in patients with the anxiety/hyperventilation syndrome. Oxygen therapy should be initiated in patients with severe hypoxemia. Patients with life-threatening alkalosis (pH >7.60), particularly if it is a mixed respiratory and metabolic condition and they have complications such as arrhythmia or seizures can require mechanical ventilation with sedation and/or paralysis to control hyperventilation.

Respiratory alkalosis in patients receiving mechanical ventilation is usually iatrogenic. It can often be corrected by decreasing either the set respiratory rate or tidal volume, although other measures can also be employed. The use of a capnograph and spirometer in the breathing circuit enables a more precise adjustment of the ventilator settings. Another method of treating respiratory alkalosis is to increase the amount of dead space in the ventilator circuit by placing a known length of tubing between the artificial airway and the “Y” piece of the ventilator. This results in “rebreathing” of expired gas, and therefore an increase in the inspired carbon dioxide concentration, which should increase the carbon dioxide tension of the patient, correcting the respiratory alkalosis. In patients breathing more rapidly than the ventilator settings, sedation with or without paralysis can be employed.

**RESPIRATORY ACIDOSIS**

**Pathophysiology**

Respiratory acidosis occurs when the lungs fail to excrete carbon dioxide resulting in a lower pH. This can be the result of conditions that centrally inhibit the respiratory center, diseases that interfere with pulmonary perfusion or neuromuscular function, and intrinsic airway or parenchymal pulmonary disease (Table 61–12). Acute respiratory acidosis with hypoxemia, hypercarbia, and acidosis is life-threatening. Those disorders that produce an increase in Pa\textsubscript{CO}\textsubscript{2} and hypoxemia to a degree compatible with life (e.g., chronic obstructive pulmonary disease), with or without oxygen therapy, can result in chronic respiratory acidosis (Table 61–13). These patients can function normally without noticeable neurologic

**Laboratory Tests**

- Serum chloride concentration is usually slightly increased.
- Serum ionized calcium, potassium, and phosphorus concentration can be decreased.
defects with PaCO₂ concentrations in the range of 90 to 100 mm Hg (12–13.3 kPa) (normal, 40 mm Hg [5.3 kPa]), provided adequate oxygenation is maintained.  

### Clinical Presentation

Respiratory acidosis can produce neurologic symptoms, including altered mental status, abnormal behavior, seizures, stupor, and coma. Hypercapnia can mimic stroke or CNS tumors by producing headache, papilledema, focal paresis, and abnormal reflexes. These CNS symptoms are attributable to the vasodilator effects of CO₂ in the brain that result in an increase in cerebral blood flow.  

The degree to which cardiac contractility and heart rate are altered depends on the severity of the acidosis and the rapidity with which it develops. Modest acute hypercapnia (PaCO₂ of 50–55 mm Hg [6.7–7.3 kPa]) stimulates a stress-like response, with elevated catecholamines and corticosteroid hormone levels, and can result in increased cardiac output and pulmonary artery pressure.  

As the severity increases, cardiac output declines and vascular resistance decreases leading to refractory hypotension in some patients.  

In respiratory acidosis, the serum potassium concentration increases modestly secondary to cellular shifts. The increases are less than those seen with inorganic metabolic acidosis and are difficult to predict for individual patients (see Chapter 60).  

### Laboratory Tests

- Serum potassium concentration can be modestly increased. Hypercapnia can be moderate (PaCO₂ of 50–55 mm Hg [6.7–7.3 kPa]) to severe (PaCO₂ of >80 mm Hg [>10.6 kPa]). Hypoxia (PaO₂ is <70 mm Hg [<9.3 kPa]) is often present.

### Compensation

The body responds to acute respiratory acidosis with chemical buffering. The increase in PaCO₂ results in increased carbonic acid levels. The carbonic acid dissociates, releasing hydrogen ions, which are buffered by nonbicarbonate buffers (i.e., proteins, phosphate, and hemoglobin) and bicarbonate. Thus, on the basis of physicochemical factors, increases in PaCO₂ raise the serum bicarbonate concentration. In general, in acute respiratory acidosis, the bicarbonate concentration increases by 1 mEq/L (1 mmol/L) above 24 for each 10-mm Hg (1.3 kPa) increase in PaCO₂ above 40 (5.3 kPa) (see Table 61–7).

Metabolic compensation occurs when respiratory acidosis is prolonged beyond 12 to 24 hours. In response to hypercapnia and acidemia, proximal tubular bicarbonate reabsorption, ammoniagenesis, and distal tubular hydrogen secretion are enhanced, resulting in an increase in the serum bicarbonate concentration that raises the pH toward normal. Renal compensation for chronic hypercapnia generally results in the plasma bicarbonate concentration increasing by 4 mEq/L (4 mmol/L) above 24 for each 10-mm Hg (1.3 kPa) increase in PaCO₂ above 40 (5.3 kPa) (see Table 61–7). The new steady state in acid–base values is generally achieved within 5 days of the onset of hypercapnia in dogs; the time interval necessary for compensation in humans has not been established.

### Treatment

#### Respiratory Acidosis

The treatment of respiratory acidosis is dependent on the chronicity of the patient’s condition. Respiratory decompensation in patients with chronic elevations in PaCO₂ are frequently seen in those with acute infections and those recently started on narcotic analgesics or oxygen therapy.  

Aggressive treatment of these conditions can offer considerable benefit and should be initiated. Furthermore, tranquilizers and sedatives should be avoided and supplemental oxygen, if used, should be minimized.

#### Acute Respiratory Acidosis

When carbon dioxide excretion is severely impaired (PaCO₂ >80 mm Hg [>10.6 kPa]) and/or life-threatening, hypoxia is present (PaO₂ <40 mm Hg [<5.3 kPa]), the immediate therapeutic goal is to provide adequate oxygenation. Under these circumstances, hypoxia, not acidemia, is the principal threat to life. A patent airway needs to be established, which can necessitate intubation. Excessive secretions must be cleared from the airway and oxygen administered to restore adequate oxygenation. Mechanical ventilation is usually required.

The underlying cause of the acidosis should be treated aggressively (e.g., bronchodilators for treatment of severe bronchospasm; narcotic or benzodiazepine antagonists to reverse the deleterious effects of these agents on the respiratory center). Bicarbonate administration is rarely necessary in the treatment of respiratory acidosis. Furthermore, rapid correction of acidosis with bicarbonate can eliminate the patient’s respiratory drive or precipitate metabolic alkalosis. Cautious use of alkali (bicarbonate or THAM) can restore the responsiveness of bronchial muscles to β-adrenergic agonists and thus can be beneficial for those patients with severe bronchospasm.  

Arterial blood gases should be monitored closely to ensure that the respiratory acidosis is resolving without creating a metabolic alkalosis as the result of compensatory elevation in HCO₃⁻ and decrease in PaCO₂. Arterial blood gases should be obtained every 2 to 4 hours during the acute phase and less frequently (every 12–24 hours) as the acidosis improves.

#### Acute Respiratory Acidosis in a Compensated Chronic Respiratory Acidotic Patient

Patients with a history of chronic respiratory acidosis (e.g., those with chronic obstructive pulmonary disease) can experience an acute worsening of their respiratory acidosis. This can result
in severe life-threatening hypoxemia. As with acute respiratory acidosis, the goals of therapy are maintenance of a patent airway and adequate oxygenation. Individuals with chronic respiratory acidosis are routinely able to tolerate a low PaO2, and an elevated Paco2 because of compensation (increased number of red blood cells, hemoglobin content, and 2,3-diphosphoglycerate). The drive to breathe in these patients is dependent on hypoxemia rather than hypercarbia. Administration of oxygen to a patient with chronic respiratory acidosis can eliminate this drive to breathe and result in the syndrome of carbon dioxide narcosis. In this case, if the PaO2 is 50 mm Hg (6.7 kPa), no oxygen treatment is necessary. If the PaO2 is <50 mm Hg (<6.7 kPa), oxygen therapy should be initiated carefully using a controlled flow of oxygen.2

Arterial blood gases should be checked periodically to ensure adequate oxygenation. If the Paco2 increases during oxygen therapy, it can be a sign of impending carbon dioxide narcosis and oxygen therapy may need to be discontinued. The underlying cause of the acute exacerbation should be aggressively managed. Pulmonary infections should be treated with the appropriate antibiotics and bronchodilators administered as necessary. Excess secretions should be cleared from the airway to allow proper gas exchange. This can involve increasing oral fluid intake to decrease the viscosity of secretions, deep breathing, and postural drainage, suction, or bronchoscopy.

MIXED ACID–BASE DISORDERS

DIAGNOSIS

The diagnosis of a mixed disorder depends on an understanding of the appropriate quantitative response of the compensatory mechanisms for each of the simple acid–base disturbances. To diagnose mixed disorders, one must know how each of the four simple disorders alters pH, Pa co 2 , and [HCO 3 −] (see Table 61–7). If a given set of blood gases does not decrease within the range of expected responses for a simple acid–base disturbance, a mixed disorder should be suspected. In addition to laboratory information, a thorough history and physical examination of the patient will often lead to the diagnosis, even before the laboratory data are available. Examples of common mixed disturbances follow.

Mixed Respiratory Acidosis and Metabolic Acidosis

In mixed respiratory and metabolic acidosis, there is a failure of compensation. The respiratory disorder prevents the compensatory decrease in Paco2 expected in the defense against metabolic acidosis. The metabolic disorder prevents the buffering and renal mechanisms from raising the bicarbonate concentration as expected in the defense against respiratory acidosis. In the absence of these compensatory mechanisms the pH decreases markedly.

Mixed respiratory and metabolic acidosis may develop in patients with cardiopulmonary arrest, in those with chronic lung disease who are in shock, and in metabolic acidosis patients who develop respiratory failure. When treating this mixed disorder, clinicians need to respond to both the respiratory and metabolic acidosis. Improved oxygen delivery must be initiated to improve hypercarbia and hypoxia. Mechanical ventilation may be needed to reduce Paco2. During the initial stage of therapy, appropriate amounts of alkali should be given to reverse the metabolic acidosis (see Treatment, Metabolic Acidosis above).

Mixed Respiratory Alkalosis and Metabolic Alkalosis

The combination of respiratory and metabolic alkalosis is the most common mixed acid–base disorder. This mixed disorder occurs frequently in critically ill surgical patients with respiratory alkalosis caused by mechanical ventilation, hypoxia, sepsis, hypotension, neurologic damage, pain, or drugs, and with metabolic alkalosis caused by vomiting or nasogastric suctioning and massive blood transfusions. It can also occur in patients with hepatic cirrhosis who hyperventilate, receive diuretics, or vomit, as well as in patients with chronic respiratory acidosis and an elevated plasma bicarbonate concentration who are placed on mechanical ventilation and undergo a rapid decrease in Paco2.

The renal excretion of bicarbonate that usually occurs as compensation for the respiratory alkalosis is prevented by the complicating metabolic alkalosis. Likewise, the retention of Paco2 expected to compensate for metabolic alkalosis is prevented by the primary respiratory alkalosis. The failure of compensation that occurs with mixed respiratory and metabolic alkalosis can result in a severe alkalemia.

Administration of sodium chloride and potassium chloride solutions will help correct the metabolic component of this disorder and adjustment of the ventilator and/or treatment of an underlying disorder that is causing hyperventilation can correct or ameliorate the respiratory component of this mixed disorder.

Mixed Metabolic Acidosis and Respiratory Alkalosis

This mixed disorder is often seen in patients with advanced liver disease, salicylate intoxication, and pulmonary-renal syndromes. The respiratory alkalosis will decrease the Paco2 beyond the appropriate range for the respiratory compensation usually seen with metabolic acidosis. The plasma bicarbonate concentration also decreases below the level expected in compensation for a simple respiratory alkalosis. In a sense, the defense of pH for either disorder alone is enhanced; thus the pH can be normal or close to normal, with a low Paco2 and a low [HCO3−]. Treatment of this disorder should be directed at the underlying cause. Because of the enhanced compensation, the pH is usually closer to normal than in either of the two simple disorders.

Mixed Metabolic Alkalosis and Respiratory Acidosis

This mixed disorder often occurs in patients with chronic obstructive pulmonary disease and chronic respiratory acidosis who are treated with salt restriction, diuretics, and possibly glucocorticoids. When diuretics are initiated, the plasma bicarbonate may increase because of increased renal bicarbonate generation and reabsorption, providing mechanisms for both generating and maintaining metabolic alkalosis. The elevated pH diminishes respiratory drive and may therefore worsen the respiratory acidosis.

Although the pH may not deviate significantly from normal, treatment may need to be initiated to maintain PaO2 and Paco2 at acceptable levels. Because it is often difficult to correctly identify this mixed disorder, it is helpful to observe the patient’s response to discontinuation of diuretics and administration of sodium and potassium chloride.3 If the patient has a simple metabolic alkalosis, the Paco2 will normalize, but it will only minimally affect the Paco2 if it is a mixed disorder. Treatment should be aimed at decreasing the plasma bicarbonate with sodium and potassium chloride therapy, thereby allowing the renal excretion of retained bicarbonate from the diuretic-induced metabolic alkalosis. This therapy should be used cautiously to avoid exacerbating any underlying congestive heart failure.

EVALUATION OF THERAPEUTIC OUTCOMES

Because acid–base disorders are such a common and widespread problem, pharmacists can play a key role in identifying, preventing, and properly treating acid–base abnormalities. Acid–base disorders do not occur only in the intensive care unit setting. Patients in ambulatory and
extended care settings have many chronic conditions and drug therapies that commonly affect acid–base balance. Thus pharmacists in all practice settings should use their knowledge to identify patients at high risk for developing drug-related problems which affect acid–base balance and to undertake appropriate prevention and treatment measures to improve the quality of life of the patients they care for.

**ABBREVIATIONS**

BW: body weight  
CNS: central nervous system  
DCA: dichloroacetate  
ECF: extracellular fluid  
H+: hydrogen ion  
HCO₃⁻: bicarbonate  
H₂CO₃: carbonic acid  
HIV: human immunodeficiency virus  
NH₄⁺: ammonium  
Paco₂: partial pressure of carbon dioxide from arterial blood  
Pao₂: partial pressure of oxygen from arterial blood  
pH: the negative logarithm (base 10) of the hydrogen ion concentration  
pK: the negative logarithm of the dissociation constant  
Pvco₂: partial pressure of carbon dioxide from venous blood  
Pvo₂: partial pressure of oxygen from venous blood  
RTA: renal tubular acidosis  
SAG: serum anion gap  
THAM: tromethamine (Tris[hydroxymethyl]-aminomethane)  
UCs: unmeasured cations  
UAs: unmeasured anions

KEY CONCEPTS

1. The clinical neurologic history and examination are the cornerstones of neurologic diagnosis and management.
2. Through the patient’s history one can determine the main symptoms, the mode of onset (gradual or sudden), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses/risk factors.
3. The neurologic examination is directed at localization of the disease process so that evaluation and management may be planned appropriately.
4. The neurologic examination of a specific patient may be adapted to the patient’s specific deficit. For example, a patient with double vision may warrant an extensive cranial nerve examination but a less extensive assessment of finger strength.

To contribute most effectively to the care of patients with neurologic illness, one must understand the tools used in the diagnosis and management of these patients. In addition, clinicians must be able to gather their own data through a targeted neurologic examination and history taking to ensure optimal pharmacotherapy in neurologic patients. Despite technologic advances that have led to the development of sensitive diagnostic tests in neuroscience, the clinical neurologic history and examination are still the cornerstones of the neurologic diagnosis and management.1

SIGNS AND SYMPTOMS

1. As in all of medicine, obtaining an accurate and complete history is of utmost importance in the evaluation of neurologic diseases. In many instances, the diagnosis can be made on the basis of the history, and the neurologic examination can be tailored to optimally evaluate the patient and confirm the diagnosis. The clinician depends on the patient or family for the details of the illness. Care must be taken to avoid “leading” the patient. Obtaining an accurate history may be difficult because a number of neurologic diseases may affect patients’ speech and memory.

THE NEUROLOGIC EXAMINATION

1. An assessment of patient effort is necessary to interpret the results of the neurologic examination. It can identify any abnormalities, particularly asymmetry of function, and help to localize the lesion within the nervous system (central versus peripheral and specific location within the central nervous system [CNS] or the peripheral nervous system). The neurologic examination consists of six main components: higher cortical function (mental status), cranial nerves, motor function, reflexes, sensory function, and gait. Table 62–1 describes the common approaches to assessing each of the six domains and includes examples of the diseases in which abnormal findings are common.

PROCEDURES USED IN THE DIAGNOSIS

In addition to the neurologic examination, certain imaging techniques and procedures may be essential in the diagnosis of neurologic disorders. Lumbar puncture is used to obtain cerebrospinal fluid for examination for infection, and imaging studies, such as computed tomography (CT) and magnetic resonance imaging (MRI), are used to determine the location and extent of lesions.
The Neurologic Examination

Cranial Nerve Function and Examples of Testing

Electromyography (EMG) and nerve conduction velocities (NCVs) are used to assess the function of the peripheral nerves, neuromuscular junction, and muscles. NCVs are measured by stimulating the nerve and recording the speed of conduction of the impulse. NCVs can be used to detect the presence of localized peripheral nerve injuries (e.g., carpal tunnel) or diffuse symmetric neuropathies (which may be inherited or acquired). EMG assesses muscle dysfunction as a result of primary muscle disease or secondary to nerve injury. This test is used to diagnose peripheral neuropathies (inherited and acquired), Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, radiculopathies, and muscle diseases.

The cerebral circulatory system can be imaged or evaluated in a number of different ways depending on the type and location of the abnormality suspected. Imaging techniques can be used to identify local arterial stenosis, aneurysms, or arteriovenous malformations. Atherosclerosis of the extracranial arteries, a frequent cause of stroke, can be evaluated using ultrasound (referred to as duplex sonography, carotid Doppler, or color-flow Doppler), magnetic resonance angiography (MRA), spiral computed tomographic angiography (CTA), or intraarterial angiography. The intracranial arterial circulation can be evaluated using transcranial Doppler, MRA, CTA, or intraarterial angiography. Each technique has its own advantages and disadvantages. Intraarterial angiography provides the best imaging of the smaller arteries of the cerebral circulation but is more invasive than the other measures.

Computed tomography (CT) uses x-rays to produce images of “slices” of the brain that are 1 to 10 mm in thickness. CT revolutionized the practice of neurology by allowing direct imaging of the brain anatomy. CT is currently available in most communities and is used to evaluate patients with intracranial disease. CT scans are used to identify tumors, hemorrhages, infarctions, hydrocephalus, and atrophy. Intravenous contrast agents (a contrast-enhanced scan) can be administered to enhance the image of blood vessels and areas of blood–brain barrier damage that may be caused by abscesses, other inflammatory conditions, tumors, or stroke.

Magnetic resonance imaging (MRI) uses the magnetic properties of the hydrogen atom nucleus and proton to produce computer-processed scans that provide improved anatomic detail when compared with CT scans. MRI offers the advantages of better differentiating between white and gray matter and delineating lesions close to bone (brainstem and cerebellum) and has no radiation risk.

however, it is not as readily available as CT and is more expensive. MRI has a proven advantage over CT in evaluating lesions in the posterior fossa and in detecting lesions in the white matter, such as plaques in multiple sclerosis. MRI is also useful in the diagnosis of tumors and very early ischemic stroke (diffusion-weighted imaging). Imaging of the spinal canal and its contents can be accomplished either by MRI myelography or CT myelography.

Other imaging techniques such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are considered tests of brain function. These tests are being studied extensively in epilepsy as well as in cerebrovascular disorders, cerebral tumors, movement disorders, and dementia. PET scans use a positron-emitting isotope to display chemical activity and the rates of biologic processes within the brain. This method can assess regional metabolic changes in the brain. The expense, technical complexity (a cyclotron is needed), and limited availability of this technique limit its clinical usefulness.

SPECT scans measure radiotracer uptake by tissues and provide cross-sectional images of the brain. This technique has been used extensively to assess cerebral blood flow. Although the resolution of SPECT is not as good as PET, the availability has led to wide clinical use in disorders such as stroke, dementia, and epilepsy.

**CONCLUSION**

Assessment of the patient with neurologic disease is challenging. The patient by virtue of the neurologic deficit, may or may not be able to provide reliable information regarding medication history or extent of illness. The clinician must develop alternate strategies to obtain a complete data set and develop a pharmacotherapy plan. Ability to interpret and synthesize the results of the neurologic examination and other diagnostic tests will help a great deal in this quest.

Alzheimer’s Disease

EPIEMIOLOGY

1. AD is the most common cause of dementia, accounting for 50% to 60% of cases of late-life cognitive dysfunction. Its prevalence among dementia patients increases to 80% if AD lesions in conjunction with other pathologic brain lesions are considered.

Table 63-1 lists the most common types of dementia among older adults. Dementia in an individual can result from multiple etiologies. This chapter focuses exclusively on dementia of the Alzheimer’s type. However, the reader is encouraged to use the nonpharmacologic approaches and management of behavioral problems outlined in this chapter as a general treatment approach for other types of dementia that may share similar features with AD.

Approximately 5.3 million Americans have AD. By the year 2050, 1 in 5 people will be older than age 65 years, and the number of AD patients is projected to be 13.2 million. Most cases present in persons older than age 65 years, but approximately 5% of cases occur in persons younger than age 65 years. Onset can be as early as age 40 years, resulting in the arbitrary age classifications of early onset (age 40–64 years) and late onset (age 65 years and older).

Increasing age is the greatest risk factor for AD. The prevalence of AD increases exponentially with age, affecting approximately 7% of individuals age 65 to 74 years, 53% of those age 75 to 84 years, and 40% of persons age 85 years and older. Genetic inheritance is also a significant risk factor, although other factors may contribute. Factors determining age of onset and rate of progression remain largely undefined.

Data from Reisberg,90 Rubin,46 and Chapman et al47

Alzheimer’s disease (AD), first characterized by Alois Alzheimer in 1907, is a gradually progressive dementia affecting cognition, behavior, and functional status. The exact pathophysiologic mechanisms underlying AD are not entirely known, and no cure exists. Although drugs may reduce AD symptoms for a time, the disease is eventually fatal.

AD profoundly affects the family as well as the patient. The need for supervision and assistance increases until the late stages of the disease, when AD patients become totally dependent on a family member, spouse, or other caregiver for all of their basic needs. These are the all-too-common experiences of the millions of people in the United States who care for someone with AD.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

Neurologic Disorders

SECTION 6

Neurologic Disorders

ETIOLOGY AND GENETICS

The exact etiology of AD is unknown; however, several genetic and environmental factors have been explored as potential causes of AD. Dominantly inherited forms of AD account for less than 1% of cases. More than half of early-onset, dominantly inherited cases of AD. Dominantly inherited forms of AD account for less than 1% and environmental factors have been explored as potential causes.

Survival following AD diagnosis is typically 4 to 6 years. AD is the fifth leading cause of death for those age 65 years and older in the United States. AD may not cause death directly. The most common cause of death in patients with AD is pneumonia, possibly resulting from eating problems in the terminal stage of the disease.

ENVIRONMENTAL AND OTHER FACTORS

A number of environmental factors are associated with an increased risk of AD, including age, decreased reserve capacity of the brain (reduced brain size, low educational level, and reduced mental and physical activity in late life), head injury, Down syndrome, depression, herpes simplex, and risk factors for vascular disease (hypercholesterolemia, hypertension, atherosclerosis, coronary heart disease, elevated homocysteine, obesity, and diabetes). Whether these vascular risk factors are true causal risk factors for AD contributing to AD pathology, or whether they result in cerebrovascular pathology that, in turn, contributes to the symptoms of AD, remains to be established.

The incidence of AD rises with increasing age, so that among centenarians the histopathologic and clinical changes needed to justify a diagnosis of AD probably coexist in more than 90% of these individuals. One oft-quoted study concluded that almost half those older than age 85 years have AD. AD may develop in individuals over the course of decades, suggesting that AD is a distinct disease or part of aging remains unresolved. An in-depth discussion of the aging—AD controversy is not possible in this chapter; it is reviewed elsewhere.

PATHOPHYSIOLOGY

The signature lesions in AD are neuritic plaques and neurofibrillary tangles (NFTs) located in the cortical areas and medial temporal lobe structures of the brain. Along with these lesions, degeneration of neurons and synapses, as well as cortical atrophy occurs. Plaques and NFTs may also be present in other diseases, even in normal aging, but at least in younger demographics there tends to be a higher burden of plaques and NFTs in AD-affected subjects than there is in age-matched controls. Several mechanisms have been proposed to explain changes in the brain that result in the symptoms of AD, including misfolding of proteins (βAβ aggregation and deposition leading to the formation of plaques and hyperphosphorylation of tau protein leading to NFT development); synaptic failure and depletion of neurotrophin and neurotransmitters; and mitochondrial dysfunction (oxidative stress, impaired insulin signaling in the brain, vascular injury, inflammatory processes, loss of calcium regulation, and defects in cholesterol metabolism).

AMYLOID CASCADE HYPOTHESIS

Neuritic plaques (also termed amyloid or senile plaques) are extracellular lesions found in the brain and cerebral vasculature. Plaques from AD brains largely consist of a protein called β-amyloid...
protein (Aβ). Aβ peptides consisting of 36 to 43 amino acids are produced via processing of a larger protein, APP. Aβ42 is less common than other Aβ peptides, but is prone to aggregation and plaque formation. The amyloid cascade hypothesis states that there is an imbalance between the production and clearance of Aβ peptides resulting in aggregation that causes accumulation of Aβ and ultimately leading to AD. Studies on the genetic forms of AD, including early-onset AD and Down syndrome led to the formulation of the amyloid cascade hypothesis. The amyloid cascade hypothesis has substantially evolved since it was initially proposed. While Aβ sequestered in plaques was at first believed to represent the critical toxic species, more recent versions of the hypothesis assume Aβ that is not sequestered in plaques actually drives the disease. Even so, the amyloid cascade hypothesis seems most applicable in cases of early-onset, autosomal dominant AD. However, such cases comprise less than 1% of AD, and it is not clear whether it is reasonable to etiologically extrapolate to the late-onset form (which afflicts the vast majority of those affected). Whether individuals with late-onset AD also carry genetic variations that promote a primary Aβ amyloidosis remains to be shown. If this turns out not to be the case, the possibility that amyloidosis in late-onset AD is secondary to a more upstream event will require consideration. Before this conceptual conundrum is laid to rest, however, the amyloid cascade hypothesis will likely undergo a therapy-based practical test. If treatments that efficiently reduce βAP production or remove brain βAP fail to arrest disease progression, it would argue amyloidosis is not the primary pathology in most of those with AD.

NEUROFIBRILLARY TANGLES

As Aβ was being identified in plaques, other researchers showed that NFTs are commonly found in the cells of the hippocampus and cerebral cortex in persons with AD and are composed of abnormally hyperphosphorylated tau protein. Tau protein provides structural support to microtubules, the cell’s transportation and skeletal support systems. When tau filaments undergo abnormal phosphorylation at a specific site, they cannot bind effectively to microtubules, and the microtubules collapse. Without an intact system of microtubules, the cell cannot function properly and eventually dies. The density of the NFTs correlates well with the severity of the dementia, because they are a hallmark of neuronal death. NFTs are found in other dementing illnesses besides AD, and may represent a common method by which various inciting factors culminate in cell death.

INFLAMMATORY MEDIATORS

Inflammatory or immunologic paradigms are often viewed as a corollary of the amyloid cascade hypothesis. Certainly, brain amyloid deposition associates with local inflammatory and immunologic alterations. This line of observation led some to propose that inflammation is relevant to AD neurodegeneration. The inflammatory/immunologic hypotheses argue that although Aβ may have direct neurotoxicity, at least some of its toxicity might actually be an indirect consequence of an Aβ protofibril-induced microglia activation and astrocyte reaction. This inflammatory response may represent an attempt to clear amyloid deposition. However, it is also associated with release of cytokines, nitric oxide, and other radical species, and complement factors that can both injure neurons and promote ongoing inflammation. Indeed, levels of multiple cytokines and chemokines are elevated in AD brains, and certain proinflammatory gene polymorphisms are reported to be associated with AD.

Consistent with these molecular observations are epidemiologic data suggesting that exposure to nonsteroidal antiinflammatory drugs (NSAIDs) may reduce AD risk. However, multiple prospective short duration trials of NSAIDs in AD prevention and of NSAIDs as AD treatment have been therapeutically disappointing. Interestingly, the conceptual impetus for trying NSAIDs in AD has radically shifted in recent years. Rather than postulate that clinical benefits (if any are shown to exist) might derive from an antiinflammatory effect, current thinking is that any observed benefits would reflect the ability of some NSAIDs to alter APP processing away from its 42-amino-acid degradation product (Aβ42).

THE CHOLINERGIC HYPOTHESIS

Multiple neuronal pathways are destroyed in AD. Neuronal damage can be seen in conjunction with plaque structures. Widespread cell dysfunction or degeneration results in a variety of neurotransmitter deficits, with cholinergic abnormalities being the most prominent. Loss of cholinergic activity correlates with AD severity. In late AD, the number of cholinergic neurons is reduced, and there is loss of nicotinic receptors in the hippocampus and cortex. Presynaptic nicotinic receptors control the release of acetylcholine, as well as other neurotransmitters important for memory and mood, including glutamate, serotonin, and norepinephrine.

The discovery of vast cholinergic cell loss led to the development of a cholinergic hypothesis linked to the pathophysiology of AD. The cholinergic hypothesis targeted cholinergic cell loss as the source of memory and cognitive impairment in AD. Consequently, it was presumed that increasing cholinergic function would improve symptoms of memory loss. This approach is flawed for two reasons. First, cholinergic cell loss appears to be a secondary consequence of Alzheimer’s pathology, not the disease-producing event; second, cholinergic neurons are only one of many neuronal pathways destroyed in AD. It is increasingly clear that simple addition of acetylcholine cannot compensate for the loss of neurons, receptors, and other neurotransmitters lost during the course of the illness. Thus the goal is to minimize or improve symptoms through augmentation of neurotransmission at remaining synapses.

OTHER NEUROTRANSMITTER ABNORMALITIES

Although the cholinergic system has received particular attention in AD pharmaceutical research, deficits also exist in other neuronal pathways. For example, serotonergic neurons of the raphe nuclei and noradrenergic cells of the locus ceruleus are lost, while monoamine oxidase type B activity is increased. Monoamine oxidase type B is found predominantly in the brain and in platelets, and is responsible for metabolizing dopamine. In addition, abnormalities appear in glutamate pathways of the cortex and limbic structures, where a loss of neurons leads to a focus on excitotoxicity models as possible contributing factors to AD pathology.

Glutamate is the major excitatory neurotransmitter in the cortex and hippocampus. Many neuronal pathways essential to learning and memory use glutamate as a neurotransmitter, including the pyramidal neurons (a network of neurons with long axons carrying information out of the cortex), hippocampus, and entorhinal cortex. Glutamate and other excitatory amino acid neurotransmitters have been implicated as potential neurotoxins in AD. In experimental models if glutamate is allowed to remain in the synapse for extended periods of time, it can destroy nerve cells. Toxic effects are thought to be mediated through increased intracellular calcium and accumulation of intracellular free radicals. Dysregulated glutamate activity is thought to be one of the primary mediators of neuronal injury after stroke or acute brain injury. Although intimately involved in cell injury, the role of excitatory amino acids in AD is as yet unclear; however, blockade of N-methyl-D-aspartate (NMDA)
receptors decreases activity of glutamate in the synapse and may hypothetically lessen the degree of cellular injury in AD.

**BRAIN VASCULAR DISEASE AND HIGH CHOLESTEROL**

There is growing evidence of a causal association between cardiovascular disease and its risk factors and the incidence of AD. Cardiovascular risk factors that are also risk factors for dementia include hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, and, particularly, diabetes. Brain vascular disease may augment the cognitive impairment observed for a given amount of AD pathology in the brain. Dysfunctional blood vessels may impair nutrient delivery to neurons and reduce clearance of $\beta$ from the brain. In addition, vascular disease may accelerate amyloid deposition and increase amyloid toxicity to neurons. Controlling high blood pressure is associated with reduced rate of progression of dementia. Diabetes may increase the risk of dementia through factors related to “metabolic syndrome” (dyslipidemia and hypertension), effects of potentially toxic glucose metabolites on the brain and vasculature, and through insulin itself. Disturbances in insulin-signaling pathways, both in the periphery and the brain, have been linked to AD. Insulin may also regulate the metabolism of $\beta$ and tau protein.

Research has found multiple links between cholesterol and the occurrence of AD. Apolipoprotein E is a lipoprotein that is synthesized in the liver, central nervous system, and cerebrospinal fluid. It is responsible for transporting cholesterol into the brain through low-density lipoprotein into neurons and binds to NFTs. Apo E4 is associated with increasing deposition of $\beta$ and is thought to act as an accelerating modulator in the course of vascular dementia. The elevated cholesterol levels in brain neurons may alter membrane functioning and result in the cascade leading to plaque formation and AD.

**OTHER MECHANISMS**

Other hypotheses proposed to explain AD pathogenesis include oxidative stress, mitochondrial dysfunction, and postmenopausal loss of estrogen in women. Each of these mechanisms may contribute to AD pathogenesis, but the extent of the contribution is uncertain. There is a growing body of evidence of a role for oxidative stress and the accumulation of free radicals in the brain of AD patients. Some epidemiologic studies suggest vitamin E, and possibly the combination of vitamin E and vitamin C, may reduce AD risk while others do not. Mitochondrial dysfunction may result in disruption of energy metabolism in the neuron. Estrogen is thought to be involved in promoting neuronal growth, and in preventing oxidative damage, which would benefit cells exposed to $\beta$. Estrogen receptors are present in the brain, and are distributed in a pattern consistent with areas destroyed in AD. Estrogen may be important in maintaining normal cholinergic neurotransmission. Estrogen may also increase NMDA receptor numbers in brain areas involved in recording new memories and prevent cell damage by acting as an antioxidant. Additional mechanisms postulated for estrogen’s involvement in maintaining memory function are related to the fact that it increases cerebral blood flow and glucose use, reduces plasma levels of Apo E, and blunts stress-related glucocorticoid release. Postmenopausal loss of estrogen may, therefore, impact maintenance of memory functions.

A single common mechanism for producing AD does not exist. Regardless of the source, however, the features remain the same: degeneration of neurons in higher brain areas; accumulation of NFTs and neuritic plaques; profound destruction of cholinergic pathways; and an insidious dementia, slowly progressive until death.

### TABLE 63–2 STAGES OF ALZHEIMER’S DISEASE

<table>
<thead>
<tr>
<th>Stage</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mild (MMSE score 26–18)</td>
<td>Patient has difficulty remembering recent events. Ability to manage finances, prepare food, and carry out other household activities declines. May get lost while driving. Begins to withdraw from difficult tasks and to give up hobbies. May deny memory problems.</td>
</tr>
<tr>
<td>Moderate (MMSE score 17–10)</td>
<td>Patient requires assistance with activities of daily living. Frequently oriented with regard to time (date, year, season). Recall for recent events is severely impaired. May forget some details of past life and names of family and friends. Functioning may fluctuate from day to day. Patient generally denies problems. May become suspicious or tearful. Losses ability to drive safely. Agitation, paranoia, and delusions are common.</td>
</tr>
<tr>
<td>Severe (MMSE score 9–0)</td>
<td>Patient loses ability to speak, walk, and feed self. Incontinent of urine and feces. Requires care 24 hours a day, 7 days a week.</td>
</tr>
</tbody>
</table>

Notes: MMSE—Mini-Mental Status Examination. Data from Burns and Iliffe, Alzheimer’s Association, Rubin.

### CLINICAL PRESENTATION OF ALZHEIMER’S DISEASE

#### General
- The patient may have vague memory complaints initially, or the patient’s significant other may report that the patient is “forgetful.” Cognitive decline is gradual over the course of illness. Behavioral disturbances may be present in moderate stages. Loss of daily function is common in advanced stages.

#### Symptoms

**Cognitive**
- Memory loss (poor recall and losing items)
- Aphasia (circumlocution and anoma)
- Apraxia
- Agnosia
- Disorientation (impaired perception of time and unable to recognize familiar people)
- Impaired executive function

**Noncognitive**
- Depression, psychotic symptoms (hallucinations and delusions)
- Behavioral disturbances (physical and verbal aggression, motor hyperactivity, uncooperativeness, wandering, repetitive mannerisms and activities, and combativeness)

**Functional**
- Inability to care for self (dressing, bathing, toileting, and eating)
### Laboratory Tests
- Rule out vitamin B₁₂ and folate deficiency
- Rule out hypothyroidism with thyroid function tests
- Blood cell counts, serum electrolytes, liver function tests

### Other Diagnostic Tests
- CT or MRI scans may aid diagnosis

### DIAGNOSIS

A family member often first brings memory complaints to the attention of a primary care clinician. Up to 50% of patients who meet criteria for dementia are not given a diagnosis in the primary care setting, leading some to believe that an appropriate screening tool may be helpful in aiding diagnosis and leading to earlier treatment.

Despite the phenomenon of underdiagnosis, the United States Preventive Services Task Force concluded that there are insufficient data to recommend for or against cognitive screening for AD, because it could not be determined if the benefits outweigh the risks.

Until recently the only way to confirm a clinical diagnosis of AD was through direct examination of brain tissue at autopsy or biopsy, although the recent development of in vivo plaque detection methods may change this. Several criteria have been developed for the detection and diagnosis of dementia, including the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) criteria, the Agency for Healthcare Research and Quality (AHRQ) Guidelines, the American Academy of Neurology Guidelines, the National Institute of Neurological Disorders and Stroke (NINDS) criteria, and the National Institute of Neurological Communicative Disorders and Stroke (NINCDS) and the Alzheimer’s Disease and Related Disorders Association (ADRDA) Criteria.

AD is still primarily a clinical diagnosis. The patient’s examination should suggest that cognitive decline from a previously higher baseline has occurred. The history should corroborate this, and further indicate cognitive decline has reached the point where changes in social or occupational functioning are present. It is possible to administer a sophisticated exam that defines cognitive domain strengths and weaknesses, and enables a neuroanatomic localization of the observed deficits. Ideally, evidence of defective retention memory (amnesia) will implicate bitemporal dysfunction. Evidence of parietal cortical dysfunction (visuospatial dysfunction), dorsolateral prefrontal dysfunction (executive dysfunction), or lateral temporal dysfunction (language dysfunction) should also be present. When approached in this way, the exam can indicate a pattern of cognitive decline that is consistent with what would be expected in AD, and assist with rendering a diagnosis that is as much a diagnosis of inclusion as it is of exclusion.

Objectively defining social or occupational dysfunction can prove tricky in the older patient who may be retired, and who may also lead a socialized lifestyle for reasons of frailty. For such patients, the minimal requirement is to establish a change in activities of daily living. Early on, this usually involves a change in instrumental activities of daily living (handling finances, organizing medications) rather than basic activities of daily living (hygiene, dressing). Some AD subspecialists use a detailed, standardized, semistructured interview of a nonpatient informant as the most critical piece of the diagnostic evaluation.

Almost any medication can contribute to cognitive impairment in vulnerable individuals, but certain classes of medication are more commonly implicated. Benzodiazepines and other sedative hypnotics, anticholinergics, opioid analgesics, antipsychotics, and anticonvulsants have been associated with cognitive impairment. NSAIDs, histamine H₂-receptor antagonists, digoxin, amiodarone, antihypertensives, and corticosteroids have been implicated in cases of delirium. Because medications are a reversible cause of cognitive symptoms, medication review and management are essential.

For patients who meet criteria for the dementia syndrome (whether the underlying cause is ultimately felt to be AD or not), current recommendations from the American Academy of Neurology include a neuroimaging study (computed tomography or magnetic resonance imaging), as well as a serologic evaluation that includes blood cell counts, serum electrolytes, liver function tests, a test of thyroid function, and a vitamin B₁₂ level. Earlier guidelines included a serologic test for syphilis, but this requirement has since been downgraded to optional. When circumstances suggest AD is not the leading entity on the differential diagnosis, other neurologic tests such as spinal fluid analysis or electroencephalogram can occasionally be justified. Neuropsychological testing is also optional, but can prove quite useful for the diagnosis of AD by helping to establish a neuroanatomical localization for the patient’s cognitive deficits.

Efforts to define the role of other AD diagnostic tests are ongoing. Positron emission tomography scanning may reveal a pattern of hypometabolism typical of AD (bitemporoparietal hypometabolism), but by itself the diagnostic accuracy of positron emission tomography scanning still lags behind that of the clinical examination and history. APOE genotyping by itself is also insufficient to make or break a diagnosis of AD, but demonstrating an APOE*4 allele in a suspected patient increases the specificity of the diagnosis and can help predict which patients with mild cognitive impairment are most likely to progress to a full-blown diagnosis of AD over the next several years. Unless the patient developed dementia prior to age 60 years and also had a parent that developed AD before age 60 years, presenilin 1, presenilin 2, or APP genotyping is usually not indicated.

### MILD COGNITIVE IMPAIRMENT

It has long been recognized that aging individuals experience changes in cognitive function. Mild cognitive impairment (MCI) constitutes a syndromic designation that categorizes patients with cognitive complaints insufficient to warrant a diagnosis of dementia. Persons diagnosed with MCI carry a 10% to 15% chance per year of progressing to an AD diagnosis. A logical extension of this is that what clinicians are actually seeing in most people with MCI is the initial manifestation of a progressive degenerative dementia that will eventually meet AD diagnostic criteria. However, it is important to note that not everyone meeting MCI criteria does or will have AD. As the MCI designation is increasingly applied, MCI criteria continue to evolve.

### TREATMENT

#### Alzheimer’s Disease

**DESIRED OUTCOMES**

The primary goal of treatment in AD is to symptomatically treat cognitive difficulties and preserve patient function as long as possible. Secondary goals include treating the psychiatric and behavioral sequelae that occur as a result of the disease. Current AD treatments have not been shown to prolong life, cure AD, or halt or reverse the pathophysiologic processes of the disorder.
General Treatment Approach

Clinical trials have consistently demonstrated modest benefits of early and continuous treatment with cholinesterase inhibitors. Memantine added in moderate to severe disease may also provide benefit. Following this approach allows for maximum gain and maintenance of cognition and activities of daily living. A symptomatic approach is used to treat behavioral symptoms as they arise.

 Provision of education to the patient and family at the time of diagnosis, including discussion of the course of illness, realistic expectations of treatment, and the importance of legal and financial planning, are essential to appropriate treatment. Good communication skills are important to maintain a therapeutic environment and minimize stress throughout the course of illness.

Nonpharmacologic Therapy

AD has a profound effect on both the patient and family, so appropriate treatment, both nonpharmacologic and pharmacologic, is needed. Nonmedication interventions are the current primary interventions for management of AD, and medications should be used in the context of multimodal interventions. Behavioral and psychiatric symptoms are among the most challenging and distressing symptoms of the disease and may be the determining factor in a family’s decision to seek institutional care. Symptoms such as sleep disturbances, wandering, urinary incontinence, agitation, and aggression in patients with dementia are best managed using behavioral interventions rather than medications whenever possible.

Upon initial diagnosis, the patient and caregiver should be educated on the course of illness, prognosis, available treatments, legal decisions, and quality-of-life issues. Education, including short- and long-term programs, improves caregiver knowledge and confidence, and in some cases, delays time to nursing home placement. Table 63–3 lists basic principles of care for the AD patient. Communication between the patient and family members is essential in order to minimize stress on everyone.

The general approach to developing nonmedication strategies for behavioral symptoms is to identify the symptom, identify causative factors, and adapt the caregiving environment to remedy the situation. Environmental triggers may include noise, glare, an insecure space, and too much background distraction, including television. Personal discomfort may also trigger behaviors, so it is important to monitor for pain, hunger, thirst, constipation, full bladder, fatigue, infections and skin irritation, uncomfortable temperature, fears, and frustrations. Medical comorbidity is a major source of functional and cognitive impairment in patients with AD, so general health maintenance is warranted. Interventions should redirect the patient’s attention rather than be confrontational and should specifically address known triggers. Creating a calm environment and removing stressors and triggers is key. Caregivers should be referred to support services, such as the Alzheimer’s Association, for assistance in developing nonpharmacologic strategies for managing difficult behaviors.

The caregiver must be prepared to face the changes in life that will occur, and acceptance of this does not come easily. Denial on the part of the patient and rationalization on the part of the family are common. The clinician should encourage the family to address legal and financial matters and designate a durable power of attorney for execution of financial and medical decisions once the patient is incompetent. The caregiver will need to address issues such as respite services to provide time for rest, relaxation, and conduct of personal business. Caregiver stress impacts the health and quality of life of the caregiver as well as the patient. Eventually, the caregiver will need to face critical questions with respect to institutionalization. This is probably the most difficult decision for the caregiver. Clinician support and referral to social services is vitally important in assisting the caregiver at that moment. The family should also be referred to local resources, such as the Alzheimer’s Association, that can provide detailed information regarding support services. Table 63–4 lists some referral sources for caregivers.

Education, communication, and planning are the key nonpharmacologic components of caring for an AD patient. Preparation in the early stages of illness will lessen some of the caregiver stress as the illness progresses.

Pharmacologic Therapy

Pharmacotherapy for Cognitive Symptoms

Table 63–5 presents a treatment algorithm for managing cognitive symptoms in AD. Cholinesterase inhibitors and NMDA-receptor

Table 63–3  Basic Principles of Care for the Alzheimer’s Patient

- Consider vision, hearing, or other sensory impairments.
- Find optimal level of autonomy and adjust expectations for patient performance over time.
- Avoid confrontation. Remain calm, firm, and supportive if the patient becomes upset.
- Maintain a consistent, structured environment with stimulation level appropriate to the individual patient.
- Provide frequent reminders, explanations, and orientation cues. Employ guiding, demonstration, and reinforcement.
- Reduce choices, keep requests and demands of the patient simple, and avoid complex tasks that lead to frustration.
- Bring sudden declines in function and the emergence of new symptoms to professional attention.

TABLE 63–5  Treatment Options for Cognitive Symptoms in Alzheimer’s Disease

- In mild to moderate disease, consider therapy with a cholinesterase inhibitor:
  - Donepezil or
  - Rivastigmine or
  - Galantamine
- Titrate to recommended maintenance dose as tolerated.
- In moderate to severe disease, consider adding antigu glutamatergic therapy:
  - Memantine
- Titrate to recommended maintenance dose as tolerated.
- Alternatively, consider memantine or cholinesterase inhibitor therapy alone.
- Behavioral symptoms may require additional pharmacologic approaches.

Data from Burns and Duffie, Liee et al., and Lyketsos et al.
antagonists are indicated for treatment of AD. The latest treatment guideline recommends the use of cholinesterase inhibitors for AD, with no preference for a specific agent. Donepezil, rivastigmine, and galantamine are indicated in mild to moderate AD, while donepezil is also indicated in severe disease. Memantine is indicated for moderate to severe AD; current evidence does not support its use in earlier stages of the disease. Additional benefit may be achieved when memantine is added to cholinesterase inhibitor therapy in moderate to severe AD. There is no evidence supporting combination therapy of more than one cholinesterase inhibitor.

Disagreement exists about how to determine effectiveness of treatments for AD. Selection of qualitative versus quantitative assessment may bias a clinician’s impression of response. Subtle changes are often detected only by psychometric testing rather than with routine questioning. Because no standard has been suggested to define the effectiveness of these medications, great variation exists between clinicians and the duration of treatment ranges from months to years. Realistic expectations for treatment success may include short-term improvement of symptoms and less decline in behavioral, functional, and cognitive abilities over the longer term.

Unfortunately, clinical trials have failed to provide answers to key questions in treating AD patients. Information from clinical trials is insufficient to know if a cholinesterase inhibitor dose—response relationship exists, or if additional cognitive improvement may be gained by increasing to the maximum tolerated dose, rather than continuing with the usual recommended daily dosage. Guidance in extrapolating data related to changes in cognition is needed so that a reasonable duration of clinical treatment with cholinesterase inhibitors and NMDA-antagonists can be determined.

In natural disease progression studies, scores on the Alzheimer’s Disease Assessment Scale—Cognition (ADAS-cog) have been shown to worsen (increase) by an average of 4 points over 6 months and 7 points over 1 year. Based on these findings, the general consensus is that a 4-point change in the ADAS-cog represents a clinically significant change. Therefore, if a pharmacotherapeutic agent decreases the ADAS-cog by 4 points, one could think of this as having reversed disease symptoms by 6 months. The usefulness of the ADAS-cog in clinical practice is limited because of the time required for administration; it is much more practical to assess changes in disease severity using the Mini-Mental Status Examination (MMSE).

An untreated patient has an average decline of 2 to 4 points in MMSE score per year. Consequently, successful treatment would reflect a decline of less than 2 points a year. It is reasonable to change to a different cholinesterase inhibitor if the decline in MMSE score is greater than 2 to 4 points after 1 year with the initial agent.

### Cholinesterase Inhibitors

In the early 1980s, researchers began to examine means to enhance cholinergic activity in patients with AD by inhibiting the hydrolysis of acetylcholine through reversible inhibition of cholinesterase. Tacrine was the first such drug to be examined in a systematic fashion. However, tacrine is fraught with significant side effects, including hepatotoxicity, that severely limit its usefulness. For all practical purposes the use of tacrine has been replaced by the use of safer, more tolerable cholinesterase inhibitors. The newer cholinesterase inhibitors donepezil, rivastigmine, and galantamine show similar efficacy and adverse event profiles to one another and are generally well tolerated. The most frequent adverse events associated with these agents are mild to moderate gastrointestinal symptoms (nausea, vomiting, and diarrhea). Other cholinergic side effects are generally dose related and include urinary incontinence, dizziness, headache, syncope, bradycardia, muscle weakness, salivation, and sweating. Gradual dose titration over several months can improve tolerability. Abrupt discontinuation can lead to worsening cognition and behavior in some patients. Concurrent use of anticholinergic medications with cholinesterase inhibitors should be avoided.

Table 63–6 summarizes the clinical pharmacology of the cholinesterase inhibitors. The mechanism of action differs slightly between drugs in this class. Donepezil specifically and reversibly inhibits acetylcholinesterase. Rivastigmine inhibits both butyrylcholinesterase and acetylcholinesterase. Galantamine is a selective, competitive, reversible acetylcholinesterase inhibitor and also enhances the action of acetylcholine on nicotinic receptors. The clinical relevance of these differences is unknown. Choice of cholinesterase inhibitor therapy for an individual patient is based on ease of use, patient preference, cost, and safety issues such as potential for drug interactions. In 2008, galantamine became available in generic form, which has reduced the cost of galantamine therapy. A generic form of donepezil has also been approved by the U.S. Food and Drug Administration (FDA) in December 2009, and (as of this writing) may become available as early as 2010.

Data from references 48 and 92–95.
Several cholinesterase inhibitors are now available, raising the question of whether it is appropriate to switch a patient from one to another if the first is not considered effective. Theoretical differences exist in their mechanisms of action, but many clinicians feel that these differences are not clinically meaningful, and therefore that switching is not helpful. Switching is recommended if a patient is not tolerating the initial treatment. Most clinicians probably do switch to another agent, and initial data seem to indicate that some patients do respond to an alternative cholinesterase inhibitor. Usually switching is performed without a washout period and interruptions for longer than 3 weeks are not advised.

**Antagonist Therapy** Memantine is the only NMDA-antagonist currently available. At concentrations achieved at least under in vitro conditions, memantine blocks glutamatergic neurotransmission by antagonizing NMDA receptors. Glutamate is an excitatory neurotransmitter in the brain implicated in long-term potentiation, a neuronal mechanism important for learning and memory. Under experimental conditions, blocking NMDA receptors can mitigate excitotoxic neurotoxicity and provide neuroprotection. There is currently no evidence to indicate memantine confers neuroprotection in AD.

Memantine has been studied in patients with moderate and severe AD as monotherapy and in combination with donepezil with modest favorable results on cognition and function. It is currently indicated for use in AD patients with moderate to severe illness. Studies of memantine alone and in combination with cholinesterase inhibitors in mild AD performed to date have provided insufficient evidence to support an indication for mild AD.

Memantine has 100% bioavailability regardless of administration with or without food. Protein binding is low. Memantine is not metabolized by the liver and does not inhibit cytochrome P450. Memantine is primarily excreted unchanged in the urine. The half-life ranges from 60 to 80 hours.

Overall, memantine has been well tolerated in clinical trials. The most common adverse events associated with memantine include constipation, confusion, dizziness, headache, hallucinations, coughing, and hypertension.

Memantine is likely to be used as monotherapy and also in combination with cholinesterase inhibitors in patients with moderate to severe AD. Memantine should be initiated at 5 mg once a day and increased weekly by 5 mg a day to the effective dose of 10 mg twice daily. It may be given with or without food. Dosing of 10 mg daily is recommended in patients with severe renal impairment (creatinine clearance of 5–29 mL/min [0.08 to 0.49 mL/s]).

**Role of Combination Therapy** Combination therapy with memantine added to cholinesterase inhibitor therapy is generally prescribed for patients with moderate to severe AD. The rationale for this add-on therapy is that the drug classes have different mechanisms of action. The clinical effectiveness of using combination therapy with a cholinesterase inhibitor plus memantine was compared to using a cholinesterase inhibitor alone and no treatment. This study showed significant decreases in the rate of progression of dementia across the treatment groups, such that patients who received combination therapy showed the least decline in cognitive function, followed by the group that only received cholinesterase inhibitors. The group that received combination also had the lowest rate of decline in functional status. Another combination trial assessed the efficacy and safety of memantine versus placebo in patients with moderate to severe AD already receiving stable treatment with donepezil. Patients randomized to combination therapy with memantine and donepezil showed significant improvements in cognition and function in this 6-month study. However, in patients with mild to moderate AD, there were no benefits seen when memantine therapy was added to a cholinesterase inhibitor.

Available data suggest treatment strategies currently under investigation will at best slow rather than arrest cognitive decline. It therefore seems reasonable to predict that for the foreseeable future combination therapy will become increasingly common in AD, especially as drugs or treatments with unique mechanisms of action become available, and drugs with neuroprotective modes of action are concomitantly used with symptomatic drugs.

**Effect of Current Treatments on Neurodegenerative Processes** AD is a progressive disorder. Affected individuals typically experience some degree of cognitive decline and histologic change years (if not decades) before a diagnosis is made. Therefore, the ideal treatment will be one that not only reverses symptoms by enhancing cognitive function (a symptomatic treatment), but also arrests the neurodegeneration-relevant molecular processes that underlie cognitive decline (a disease-modifying treatment).

Clinical trials for AD prompt consideration of whether positive outcomes suggest either a symptomatic or disease-modifying effect. Any rapid performance improvement on cognitive ability, activities of daily living, or behavioral end points is indicative of a symptomatic effect. All cholinesterase inhibitor agents and memantine demonstrate this pattern. On the other hand, arrest of decline or a sustained reduction in the slope of decline would argue the presence of a disease-modifying effect. It has not been possible to unequivocally demonstrate this in trials of the currently approved treatments. Definitive trials evaluating whether cholinesterase inhibitors or memantine have disease-modifying effects are difficult to perform, because doing so requires continuing a placebo arm over an extended period, well beyond demonstration of symptomatic benefit. Also, subject attrition over an extended study would complicate both intent-to-treat and observed cases analyses.

With the currently approved AD drug treatments, placebo-controlled pivotal trials were followed by open-label extension studies. Published studies have lasted as long as 5 years, and as part of these studies, decline in the treatment group was compared with “projected” placebo groups based on the placebo groups followed during the 6-month randomized phase of the efficacy study, as well as natural history cohorts from the pre-cholinesterase inhibitor therapy era. Although analyses of this sort conclude that, for up to at least 5 years, persons receiving treatment exceed their projected nontreatment cognitive performance, no convincing evidence of a disease-modifying effect emerges.

Disagreement exists about the usefulness of current therapies for AD in advanced stages of the disease. Some clinicians believe that patients should be taken off cognitive-enhancing medications once they have reached very severe stages of AD, whereas others believe that these medications may continue to be helpful with managing psychiatric symptoms and maintaining function. Many clinicians discontinue cognitive-enhancing medications once the AD patient is bedridden and unable to perform activities of daily living.
Management of Brain Vascular Health
Guidelines for the principles of care of patients with AD support the management of vascular brain disease and its associated risk factors as part of the treatment of AD. There is a growing body of evidence that brain vascular disease plays an important role in the progression of dementia. For a given level of Alzheimer’s pathology, vascular disease in the brain may add to the degree of cognitive impairment. Management of brain vascular disease includes monitoring blood pressure, glucose, cholesterol, and homocysteine and initiation of appropriate interventions. Guidelines recommend initiation of low-dose aspirin therapy in patients with AD with significant brain vascular disease. Elevated homocysteine levels correlate with decreased performance on cognitive tests, but there remains insufficient evidence of a benefit of B vitamin supplementation (B6, B12, and folic acid) on cognitive function in patients with AD. Reducing the risk for developing brain vascular disease may also be an important strategy in reducing the risk for developing AD. The Alzheimer’s Association’s Maintain Your Brain campaign is designed to increase awareness of the importance of brain health as a part of healthy aging and recommends staying physically, mentally, and socially active; adopting a low-fat, low-cholesterol diet rich in dark vegetables and fruit; and managing body weight, blood pressure, cholesterol, and blood sugar to reduce the risk of heart disease, stroke, and diabetes. Appropriate management of vascular disease risk factors may reduce the risk for developing AD.

Other Potential Treatment Approaches

Estrogen
Estrogen replacement has been studied extensively for the treatment and prevention for AD. Most, but not all, retrospective epidemiologic studies show a lower incidence of AD in women who took estrogen replacement therapy postmenopausally. Prospective clinical trials have not supported the use of estrogen as a treatment for cognitive decline and longer trials tend to suggest harm. Overall, the evidence does not support the use of estrogen to treat or prevent dementia.

Antinflammatory Agents
Retrospective epidemiologic studies suggest a protective effect against AD in patients who have taken NSAIDs. The benefits of antinflammatory agents have been less compelling in prospective clinical studies. NSAIDs have had no cognitive benefit in AD patients or else benefits so minimal the risk of harm exceeds the potential benefit. Tolerance is problematic. Additionally, prednisone treatment was associated with worsening behavioral symptoms. Because there is a lack of compelling data and also a significant incidence of adverse effects, particularly gastritis and the possibility of gastrointestinal bleeds, NSAIDs and prednisone are not recommended for general use in the treatment or prevention of AD at the present time.

Lipid-Lowering Agents
A potential AD protective effect has been postulated for lipid-lowering agents, particularly the 3-hydroxy-3-methylglutaryl-coenzyme A-reductase inhibitors. Longitudinal epidemiologic studies suggest an association between elevated midlife total cholesterol levels and AD. Increased risk of dementia does not appear to be associated with hypercholesterolemia in late life however. Other studies note that the incidence of AD is lower in patients who have taken either a statin or another lipid-lowering agent, but not in patients who were taking other cardiovascular medications. It is important to note that not all epidemiologic studies suggest an association between cholesterol and AD.

Randomized controlled trials of statin therapy given in late life to patients at risk for vascular disease indicate that statins do not prevent AD. Several randomized controlled trials of statins for the treatment of mild to moderate AD have been completed or are ongoing. Thus far, these trials have not demonstrated a significant benefit of statin therapy, but results of ongoing trials should help to clarify the role of statins in the treatment of AD. Interestingly, cognitive impairment has been recognized as a rare adverse event associated with statin therapy. The extent of cognitive impairment may depend on the lipid solubility of the drug, regulating the amount of drug that is able to cross the blood—brain barrier. As simvastatin and lovastatin have the highest lipophilicity, they may be the most likely candidates to cause memory impairment. More research is needed to understand the complex relationship between cholesterol, statin therapy, and cognitive functioning. For now these agents should be reserved for patients who have other indications for their use.

Dietary Supplements

Vitamin E Based on pathophysiologic theories involving oxidative stress and the accumulation of free radicals in AD, significant interest has evolved regarding the use of antioxidants in the treatment of AD. For a period starting in the late 1990s, vitamin E was frequently recommended as adjunctive treatment for AD patients. This was based on data from the only published clinical trial to date, which evaluated the time to critical end points (i.e., death, institutionalization, loss of ability to perform activities of daily living, or severe dementia) in patients treated with vitamin E, selegeline, the combination, or placebo. Although vitamin E and selegiline were superior to placebo, this study has been criticized because of differences in baseline cognitive severity, calling the validity of the results into question. Because of vitamin E’s perceived safety (at that time) and low cost, doses of up to 2,000 IU per day were commonly recommended.

Evidence related to vitamin E’s role in prevention of AD is mixed. Epidemiologic studies in individuals without AD have yielded conflicting results, with some studies showing delay in the onset of AD in individuals taking vitamin E supplements, but others failing to find this association. Some studies have also found that dietary intake of vitamin E is associated with reduced risk, while others have not. A study in patients with mild cognitive impairment failed to show that vitamin E had a significant effect on slowing the progression to AD.

Vitamin E treatment may also be associated with risks. Side effects observed with vitamin E administration include impaired hemostasis, fatigue, nausea, diarrhea, abdominal pain, and falls. A meta-analysis found that high-dose vitamin E increases mortality in supplemented subjects. In light of these findings, vitamin E supplementation is not recommended for the treatment of AD.

Ginkgo biloba for the prevention and treatment of AD has been extensively studied. Rationales for studying Ginkgo for AD have included its potential to increase blood flow, decrease blood viscosity, antagonize platelet-activating factor receptors, increase anoxia tolerance, inhibit monoamine oxidase, and serve as an antioxidant. Active ingredients in G biloba include flavonoids, the Ginkgoflavone glycosides, and bioflavonoids. Most studies reporting benefit in patients with AD have studied a standardized extract, EGb 761, in doses of 120 mg per day for at least 4 to 6 weeks. Those advocating the use of Ginkgo for AD suggest doses of 120 to 240 mg of the standard leaf extract twice per day be used, and note 12 weeks of consistent dosing may be needed to observe an effect. However, a large trial of G biloba in which the 120 mg twice a day dose was studied did not reduce either the overall incidence rate of dementia or AD incidence in elderly individuals with normal cognition or MCI. Side effects reported from EGb 761 studies were typically mild but did include nausea, vomiting, diarrhea, headaches, dizziness, palpitations, restlessness, and weakness. Because EGb also has a potent antiplatelet effect, it should be avoided by individuals...
taking anticoagulant or antiplatelet therapies, and should be used cautiously in patients taking NSAIDs.\textsuperscript{70,72} Further, the content of retail herbal products is poorly standardized, and significant variation in purported active ingredient content can exist from lot to lot and between manufacturers. Current practice guidelines do not recommend Ginkgo for the prevention or treatment of AD.\textsuperscript{37}

Huperzine A is an alkaloid isolated from the Chinese club moss, \textit{Huperzia serrata}. It reversibly inhibits acetylcholinesterase and is administered orally in doses of 50 to 200 mcg 2 to 4 times daily. Nondefinitive clinical studies suggest huperzine A may have efficacy in the symptomatic treatment of AD, but more studies are needed to determine its place in therapy. In a medium-sized, randomized, double-blind, placebo-controlled multicenter study in patients with mild to moderate AD performed in China, treatment with huperzine A at doses of 400 mcg/day for 12 weeks resulted in improvement in cognition by an average of 4.6 points assessed by ADAS-cog ($P = 0.000$), 2.7 points on the MMSE, and 1.5 points on the Alzheimer’s Disease Assessment Scale—noncognition ($P = 0.008$).\textsuperscript{73} Replication of these study results are still pending. The current consensus is that huperzine A has not been adequately studied for use in AD, its consistency in retail products remains a concern, and potential side effects could be substantial, especially in those taking cholinesterase inhibitors.\textsuperscript{70,74} Huperzine A is not currently recommended for AD treatment.

Arguments that omega-3 fatty acids found in fish oil, such as docosahexaenoic acid, could benefit AD subjects have existed for some years. A large prospective, placebo-controlled trial of docosahexaenoic acid in AD subjects was recently reported. For the most part, results were disappointing, and although it could not be ruled out that population subsets did benefit, the primary study end points were negative.\textsuperscript{75} At the time of this chapter’s preparation, testing of other dietary supplements, such as curcumin, is ongoing.\textsuperscript{76}

Currently, the only dietary agent approved by the FDA for the treatment of AD is AC1202, which is sold under the commercial name Axona. AC1202 is a modification of medium-chain triglyceride formulations used decades ago for the treatment of pediatric epilepsy; such formulations contain mixtures of C5–C12 fatty acids. AC1202 consists primarily of the C8 fatty acid, caprylic acid. AC1202 is converted by the liver to a ketone body, betahydroxybutyrate, which is secreted into the blood stream. Betahydroxybutyrate crosses the blood—brain barrier and can be used as an oxidative phosphorylation substrate by neuron mitochondria. Due to its ability to support brain bioenergetics, which is impaired in AD, betahydroxybutyrate was first proposed as a potential AD treatment in 1989.\textsuperscript{77} Support for AC1202 efficacy in the treatment of AD comes mostly from a phase IIb trial in which subjects randomized to 40 mg per day of AC1202 for 45 days performed relatively better on the cognitive portion of ADAS-cog than did subjects randomized to a placebo.\textsuperscript{77} A subanalysis of these data revealed this benefit was entirely driven by subjects who did not have an \textit{ApoE} ɛ4 allele. For \textit{ApoE} ɛ4 carriers, ADAS-cog performance between subjects receiving AC1202 and placebo were comparable at all time points studied. Gastrointestinal-related side effects were common but in general side effects were felt to be mild. Based on these data and on the established safety track record of medium-chain triglyceride oil, in 2009 the FDA gave permission for AC1202 to be marketed as a medical food for the treatment of AD. Medical foods constitute a unique category that consists of ingestible entities specifically intended for the treatment of diseases that have “specific nutritional requirements” and in which the medical food may manipulate disease-relevant pathophysiology. Although medical foods regulatory approval standards are not nearly as rigorous as those required for approvals of new medications, medical foods are not available over-the-counter and are obtained only by prescription.

The compound tramiprosate (homotaurine), or Alzhemed, showed promise as a treatment of Alzheimer’s disease in early development. In animal studies, homotaurine demonstrated the ability to interfere with the actions of Aβ early in the amyloid cascade, subsequently preventing amyloid plaque formation and subsequent degeneration of neuronal cells. Phase III trials were disappointing, and the FDA refused to approve marketing of homotaurine as a prescription drug. Homotaurine is naturally occurring in seaweed, and its manufacturer decided to remark the product as the dietary supplement, Vivimind for age-associated memory impairment. Controversy exists between those who advocate for availability of dietary supplements to consumers and those who advocate for evidence-based medicine. The major concern is the marketing of potentially ineffective products to those suffering from memory loss or dementia.\textsuperscript{96}

### Drugs and Treatment Strategies in Development

Current drug development strategies fall broadly into one of two categories. The first category includes treatments specifically designed to reduce levels of brain Aβ or manipulate its configuration. The second category includes all other strategies.

To reduce brain amyloid levels, approaches to both reducing Aβ production and enhancing its removal have been and still are undergoing evaluation. Aβ is produced through enzymatic processing of APP by two enzyme complexes, the β- and γ-secretases. β-Secretase inhibitors have entered phase II human trials. Agents that specifically inhibit γ-secretase could prove problematic from a side-effect perspective, as γ-secretase is also critical for processing Notch3, a protein of developmental importance and perhaps brain maintenance. Certain NSAIDs (ibuprofen and flurbiprofen) influence the γ-secretase but do not inhibit it outright. In general, these NSAIDs alter where γ-secretase cuts the APP protein. An enantiomer of flurbiprofen, tarenflurbil, recently completed a large phase III efficacy trial in which no evidence of efficacy was seen.\textsuperscript{72}

Immunotherapy approaches have been studied as a way to enhance Aβ removal. The most extensive investigation involved AN1792, a Aβ-based vaccine. A phase II trial in humans was prematurely halted after a substantial percentage of those mounting a robust immune response to the vaccine experienced encephalitis, a potentially life-threatening brain inflammation. The most comprehensive, long-term clinicopathologic study of subjects receiving AN1792 later concluded vaccinated subjects show a predictable rate of cognitive decline and that despite reducing brain plaque burdens, AN1792 vaccination is unlikely to meaningfully benefit those with the common form of late-onset, sporadic AD.\textsuperscript{78}

Most proponents of the amyloid cascade hypothesis currently claim the species of Aβ that is most likely to prove relevant to AD neurodegeneration are Aβ oligomers. Aβ oligomers are formed through limited aggregation of Aβ monomers. Aβ oligomers are too small to form fibrils and may retain aqueous solubility. A drug called tramiprosate was previously created to prevent Aβ oligomer formation and tested clinically in a large phase III trial. No evidence of efficacy was seen.\textsuperscript{72} Despite these failures, the next generation of amyloid clearance therapies are currently under development. This generation includes modifications of the active immunization approach that, hopefully, will not trigger encephalitis. Passive immunization approaches via antibody infusions are also under investigation. At the time of this writing, results of a phase III trial of bapineuzumab, an Aβ antibody, are expected in 2010. The usefulness of treating
AD subjects with intravenous immunoglobulin preparations, which naturally contain antibodies to Aβ, is under evaluation.³²

The second category of AD treatment development includes efforts not specifically intended to reduce brain Aβ levels. Neuroscientists are unraveling intracellular pathways involved in cell information processing, and drugs that can modulate these pathways are under development. Drugs that retard neurobrillary tangle formation in mice expressing mutant human tau transgenes, such as valproic acid, were recently tested in humans, although no evidence of efficacy was seen. Other “anti-tangle” drugs are in various stages of development.³² The thiazolidinedione drugs rosiglitazone and pioglitazone, which reduce insulin resistance and which may also have antiinflammatory effects, were recently tested in humans with AD, although the most definitive of these trials showed no evidence of efficacy. Despite this, efforts at treating AD through modification of insulin signaling pathways are ongoing.³²

A phase II trial of latrepirdine (dimebon) recently generated much attention.⁶⁹ Suggestions of efficacy in phase II trials in no way ensures efficacy will be seen in phase III trials. This caveat seems especially pertinent in AD drug development, as phase II trials of flurbiprofen, tramiprosate, and rosiglitazone all reported some evidence of efficacy that did not bear out in phase III studies. However, in the initial 6-month placebo-controlled trial, which was conducted in Russia, AD subjects randomized to dimebon performed better on cognitive and overall performance measures than those randomized to placebo. Subjects subsequently enrolled in a 6-month open-label continuation study continued to perform above their pre-study baseline. This was the first study in which AD subjects have been reported to perform above their pre-treatment baseline over the course of a full year. At concentrations achieved in human subjects dimebon does not appear to act as a cholinesterase inhibitor or NMDA-receptor antagonist. It does not appear to reduce Aβ production and indeed in animal models appears to increase Aβ production. There are data that suggest nanomolar concentrations of dimebon affect mitochondrial function. Unfortunately, results from a phase III Dimebon study reported in Spring 2010 failed to show efficacy in the treatment of AD.

Obviously, successful development of new AD treatments depends on elucidating AD’s true underlying pathophysiology. If AD is a primary amyloidosis, as is postulated by the amyloid cascade hypothesis, then reducing Aβ would seem a rational way to proceed with drug development. If AD is not a primary amyloidosis, then the impact antiamyloid therapies have on the disease will be limited at best. Finally, at genetic and epidemiologic levels, it is now possible to define several different Alzheimer’s “diseases.” It is not unreasonable to consider whether treatments useful in one type of AD may not benefit patients with another type.

### PHARMACOTHERAPY OF NONCOGNITIVE SYMPTOMS

The majority of patients with AD manifest noncognitive symptoms at some point in the illness.⁷⁷ These symptoms can be roughly divided into three categories: psychotic symptoms, inappropriate or disruptive behavior, and depression. Effective management of these problems is important because behavioral symptoms are distressing to both the patient and the caregiver, necessitate increased caregiver supervision and patience, and are a leading reason for nursing home placement. In fact, presence of neuropsychiatric symptoms increases caregiver burden more than loss of cognition or self-care.

Strategies for treatment of psychotic or behavioral symptoms should include environmental interventions first, then pharmacologic interventions if warranted. The need for medications may exist when neuropsychiatric symptoms are of sufficient severity to cause significant distress to the patient or caregiver, interfere with function or cause disability, impede delivery of necessary care, or pose a danger to self or others.⁸⁴,⁸⁵ The balance between risks of the medication and expected benefits must be acceptable to the patient or surrogate decision maker. Medications should be used cautiously, with adequate monitoring for efficacy and adverse events.

Despite the high prevalence of noncognitive symptoms in AD, little research has been conducted in these patients. Data from clinical trials of antidepressants, cholinesterase inhibitors, and antipsychotics are now emerging, but clearly more research is needed. Because of limited clinical data, treatment is primarily empiric, with side-effect profiles used as a guide in selecting the appropriate treatment. Psychotropic medications with anticholinergic effects should be avoided because they may actually worsen cognition and interfere with cholinesterase inhibitor therapy. Other side effects in the elderly include sedation, medication-induced postural instability, and extrapyramidal side effects, which can decrease the clinical usefulness of traditional psychotropic agents.

General guidelines governing therapy can be summarized as follows: use reduced doses, monitor closely, titrate dosage slowly, and document carefully. Caregivers often have erroneous expectations regarding the effects of psychotropic medications, and the anticipated benefits and risks of therapy should be clearly explained. Disruptive behaviors and delusions wax and wane with disease progression. Attempts to slowly taper and discontinue antipsychotic medication should be undertaken regularly in minimally symptomatic patients, because some patients improve on medication withdrawal.⁹³ Table 63-7 outlines suggested doses of medications.

### Cholinesterase Inhibitors and Memantine

Clinical trials with cholinesterase inhibitors have consistently reported modest benefit in managing neuropsychiatric symptoms, although these are generally not the primary outcomes studied in the trials.⁶⁰–⁶⁲ Any benefits in symptoms such as agitation may accrue gradually over time, since cholinesterase inhibitors may not significantly reduce agitation when administered to patients experiencing acute agitation.⁹¹ Memantine shows modest behavioral benefits as well, either alone or in combination with cholinesterase

Data from Lleó et al.,⁴⁴ Benoit et al.,⁵⁷ and Grossberg and Desai.⁹³
inhibitors, and may also spare the use of antipsychotics to treat agitation.\textsuperscript{50,81} These treatments can provide modest short-term improvement and possibly slow the development and progression of behavioral symptoms. Cholinesterase inhibitors also have a small beneficial effect on caregiver burden and active time use among caregivers of persons with AD.\textsuperscript{84} These benefits should be considered along with cognitive benefits in treatment decisions. Long-term effects on behavior have not been demonstrated to date, and further research is needed.

**Antipsychotics**

Antipsychotics are widely used in the management of neuropsychiatric symptoms in AD. There is modestly convincing evidence that most of the atypical antipsychotics provide some benefit for particular neuropsychiatric symptoms, but these data have been insufficient to gain FDA approval as an indication for the management of behavioral symptoms in AD. Based on a recent meta-analysis, only 17% to 18% of dementia patients show a treatment response to atypical antipsychotics.\textsuperscript{86} In a double-blind, placebo-controlled trial of 421 outpatients with AD and psychosis, aggression, or agitation randomized to receive olanzapine, quetiapine, risperidone, or placebo for up to 36 weeks, there were no significant differences among the treatments in time to discontinuation of treatment or improvement in the Clinical Global Impression of Change scale. The investigators concluded that adverse effects offset advantages in the efficacy of atypical antipsychotic drugs for treatment of psychosis, aggression, or agitation in patients with AD.\textsuperscript{85} Adverse events are common with atypical and typical antipsychotics in patients with AD. These adverse events associated with atypical antipsychotics include somnolence, extrapyramidal symptoms, abnormal gait, worsening cognition, cerebrovascular events, and increased risk of death.\textsuperscript{86} Typical antipsychotics may also be associated with a small increased risk of death, as well as more severe extrapyramidal effects and hypotension. Chapter 76 has a more detailed discussion of antipsychotic adverse events. Overall, there is a modest expectation of treatment benefit and potential for significant harm associated with antipsychotic use in patients with AD. Individual risk and benefit must be considered when initiating therapy. Diligent monitoring during treatment is essential along with frequent reassessment of continued need.

**CLINICAL CONTROVERSY**

Antipsychotic medications have been widely used to treat disruptive behaviors and psychosis in AD patients, although the evidence supporting their modest benefit for some symptoms is limited.\textsuperscript{86} Use of antipsychotics to treat severe neuropsychiatric symptoms in AD remains controversial. Recent studies indicate that atypical and typical antipsychotics have been associated with infrequent but serious adverse events, including a small increased risk of death.\textsuperscript{81,83} These findings resulted in a FDA-mandated “black box warning” concerning the use of atypical antipsychotics in the treatment of AD. Careful consideration of risk versus benefit in individual patients is warranted.

**Antidepressants**

Depressive symptoms are common in patients with AD, occurring in as many as 50% of patients.\textsuperscript{44} Apathy may be even more frequent, but these symptoms may be difficult to distinguish in patients with dementia. Many trials have studied the efficacy of antidepressants in treating depression in patients with AD, but the results are conflicting. Small sample size, short duration of treatment, and differing measures of therapy outcomes limit comparison across studies and may account in part for conflicting study results.\textsuperscript{44} Improvement in patients receiving placebo is also common. In practice, treatment with selective serotonin reuptake inhibitors (SSRIs) is initiated most commonly in patients with AD, based on side-effect profile and evidence of efficacy.\textsuperscript{41} Among the SSRIs, the best evidence exists for sertraline and citalopram.\textsuperscript{83} Bupropion, venlafaxine, and mirtazapine may be alternatives.\textsuperscript{41} Serotonergic function may also play a role in some of the other behavioral symptoms of AD, and some studies support the use of SSRIs in the management of these behaviors, even in the absence of depression.\textsuperscript{81} Tricyclic antidepressants have efficacy similar to the SSRIs, but should generally be avoided because of their anticholinergic activity.\textsuperscript{41} There is little evidence for the use of trazodone to manage behavioral or depressive symptoms, but it is commonly recommended to treat insomnia in patients with AD.\textsuperscript{41}

Chapter 77 has a more complete discussion of treatment of depression.

**Miscellaneous Therapies**

Because antipsychotic and antidepressant therapy has shown only modest efficacy and poses a risk of undesirable side effects, medications traditionally used to treat disruptive behaviors and aggression in other psychiatric and neurologic disorders have been suggested as potential alternatives. These alternatives include benzodiazepines, buspirone, and antiepileptics.\textsuperscript{81} Benzodiazepines have been used to treat anxiety, agitation, and aggression, but the benefit is generally modest.\textsuperscript{45} Because benzodiazepines impair cognition, worsen breathing disorders, and may increase the risk of falls in AD patients, their routine use is not advised, except on an “as needed basis” for infrequent episodes of agitation.\textsuperscript{41} “Mood stabilizer” anticonvulsants such as carbamazepine, valproic acid, or gabapentin may be appropriate alternatives, but evidence is conflicting.\textsuperscript{81} Clearly, more rigorous placebo-controlled studies are needed to determine the relative efficacy and place in therapy for these medication alternatives.

Noncognitive symptoms are often the most difficult aspect of AD for the caregiver. When nonpharmacologic approaches fail, selected antipsychotics and antidepressants have been useful for effective management of behavioral, psychotic, and depressive symptoms, thereby easing caregiver burden and allowing the patient to spend additional time at home. Alternative treatments are available in case initial choices are not successful. Adverse events remain an important concern in this population.

**PHARMACOECONOMIC CONSIDERATIONS**

The economic and social costs of AD are staggering. It is the third most expensive illness in the United States after heart disease and cancer, and the majority of medical and caregiving expenses are left to the patients’ families and to government programs (state and federal). The total national cost of AD is estimated at approximately $148 billion annually.\textsuperscript{4} In 2005, annual Medicare costs were estimated at $91 billion and Medicaid costs for institutionalized AD patients were estimated at $21 billion.\textsuperscript{3} With life expectancy and the number of AD cases increasing, the cost of AD is projected to quadruple over the next 50 years.\textsuperscript{4} The potential financial burden of this disease on the healthcare system could reach crisis proportions in the near future unless more effective avenues are developed to provide care for these individuals, to prevent the disease from occurring, or to slow its progression.

Seventy-five percent of care for AD patients is provided by family and friends.\textsuperscript{4} Higher levels of home care have been associated with poorer health and higher rates of emotional stress in caregivers,
increasing the likelihood of placing patients in institutionalized care, which is considered the greatest financial cost in treating patients with AD.\(^4\) On average, the cost of yearly nursing home care is $70,000 to $77,000 per year depending on the area of the country where care is provided.\(^4\) Clearly, the greatest economic burden for the home-living AD patient is the time spent in caring for the patient, whereas in the nursing home the burden is the cost for others to provide care.

Economic data on the cost benefit of medications in AD are growing. Few studies provide prospective cost data from randomized controlled trials, and the data that does exist is for relatively short durations of therapy. Two clinical trials suggest that there is no benefit or disadvantage of donepezil compared to placebo in the cost of healthcare resource use.\(^4\) There are no similar data for galantamine or rivastigmine. One cost analysis trial of memantine found that there was a trade-off between lower costs borne by the caregiver during treatment and higher drug costs borne by the patient.\(^4\) Cost-effectiveness would be established if medications were shown to reduce the cost of care, particularly institutional care, but current randomized controlled trials have not been of sufficient duration to establish this.\(^4\) Most estimates of cost related to AD therapy are based on pharmacoeconomic models involving extrapolation of results from short-term trials, epidemiologic data, and data on resource use in various healthcare delivery models.\(^4\) Each analysis employs different assumptions and incorporates different aspects of cost, making comparisons across analyses difficult. Until long-term data are available, the true cost benefit of various treatment approaches remains unknown.

Data from current pharmacoeconomic studies in AD suggest that medication therapy may reduce costs of treating this illness; however, the true cost-effectiveness of these therapies has yet to be established. If AD treatments delay cognitive decline and time to nursing home placement, then they not only have potential economic benefit, but significant effects on the quality of life of patients and caregivers. Future studies, including prospective pharmacoeconomic trials of longer duration and more detailed cost-evaluation modeling, are needed to determine the role and benefits of pharmacotherapy on AD.

### EVALUATION OF THERAPEUTIC OUTCOMES

An evaluation of therapeutic outcomes in the patient with AD begins with a thorough assessment at baseline and a clear definition of therapeutic goals. Cognitive status, physical status, functional performance, mood, and behavior all need to be evaluated before initiation of drug therapy. The clinician should interview both the patient and the caregiver to assess response to drug therapy. In evaluating response to cognitive agents, the clinician should ask questions about the patient’s ability to perform daily functional tasks and about mood and behavior, as well as questions about memory and orientation. Objective assessments such as MMSE for cognition assessment and the Functional Activities Questionnaire for assessment of activities of daily living, can be used to quantify changes in symptoms and function.

Because target symptoms of psychiatric disorders may respond differently in dementia patients, a detailed list of symptoms to be treated should be documented in the pharmacotherapy plan to aid in monitoring. These could include, for example, “striking at spouse because patient believes spouse is an impostor,” “verbal threats and refusal to allow clothes to be changed,” and so on, as opposed to documenting vague symptoms such as “aggression” or “delusions.” To make an accurate assessment of depression, multiple symptoms (e.g., sleep, appetite, and activity and interest levels) need to be assessed in addition to the patient’s stated mood.

The patient should be observed carefully for potential side effects of drug therapy. The specific side effects to be monitored and the method and frequency of monitoring should be documented. Periodic assessments for drug effectiveness, side effects, compliance, need for dosage adjustment, and change in treatment should occur at least monthly. However, patients need to be treated for an adequate duration to see a therapeutic effect from a given intervention. Because the effects of cognition-enhancing medications are not great, a treatment period of several months to a year may be necessary before it can be determined whether therapy is beneficial. Cognitive effects of the drug are often noticed only as a plateauing during treatment or as deterioration following drug discontinuation. In general, cognitive agents should be continued if the patient is demonstrating no change in clinical status. However, if there is doubt, the medication can be slowly tapered and discontinued, and the patient monitored off the drug for 4 to 6 weeks to determine the need for continued therapy.

This page intentionally left blank
The etiology of multiple sclerosis (MS) is unknown, and currently there is no cure. Multiple sclerosis is characterized by central nervous system demyelination and axonal damage, and appears to be autoimmune in nature. Multiple sclerosis is classified by the nature of progression over time into several categories which have different clinical presentations and responses to therapy. Diagnosis of MS requires evidence of dissemination of lesions over time and in multiple parts of the central nervous system and/or optic nerve, and is made primarily on the basis of clinical symptoms and examination. Diagnostic criteria also allow for the use of magnetic resonance imaging, spinal fluid evaluation, and evoked potentials to aid in the diagnosis. Acute exacerbations or relapses of MS can be disabling. When this is the case, acute exacerbations and relapses are treated with high-dose glucocorticoids, such as methylprednisolone, intravenously, with onset of clinical response typically within 3 to 5 days. Treatment of relapsing-remitting MS with the disease-modifying therapies (DMTs) interferon β (Avonex, Betaseron, Rebif, Extavia), glatiramer acetate (Copaxone), natalizumab (Tysabri), mitoxantrone (Novantrone), and fingolimod (Gilenya) can reduce annual relapse rate, lessen severity of relapses, slow progression of changes on magnetic resonance imaging scans, slow progression of disability, and slow cognitive decline. In addition, they have been shown to reduce the likelihood of developing a second attack after a first clinically isolated syndrome consistent with MS. In most cases, treatment with DMTs should begin promptly after the diagnosis of relapsing-remitting MS, or after a clinically isolated syndrome if the brain magnetic resonance imaging is suggestive of high risk of further attacks. Natalizumab, and other choices that have been associated with problematic adverse events, should be reserved for those patients who have failed one or more standard therapies and those with poor prognostic signs.

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS) that affects approximately 1 in 200 women and somewhat fewer men in the United States. The term multiple sclerosis refers to two characteristics of the disease: the numerous affected areas of the brain and spinal cord producing multiple neurologic symptoms that accrue over time, and the characteristic plaques or sclerosed areas that are the hallmark of the disease. Although MS was first described almost 140 years ago, the cause remains a mystery, and a cure is still unavailable. Nevertheless, many advances have been made in treating and managing the complications of the disease and improving the quality of life of individuals affected by MS.

Epidemiologic aspects of MS have been reviewed in a variety of publications. MS usually is diagnosed in patients between the ages of 15 and 45 years, and the peak incidence occurs in the fourth decade of life. There are approximately 10,000 new cases diagnosed per year in the United States. Women are afflicted more than men by a ratio of approximately 2:1. Men usually develop the first signs of MS at a later age than women and are also more likely to develop the progressive form of the disease. The most important factors in the determination of risk for developing the disease are geography, age, environmental influences, and genetics. In general, disease prevalence is higher the greater the distance from the equator. Within the United States, the prevalence of MS is higher in states above the 37th parallel. Multiple sclerosis occurs more frequently
in whites of Scandinavian ancestry than in other ethnic groups. Epidemiologic and experimental data have suggested an inverse relationship between MS risk and 25-hydroxyvitamin D levels.  

ETIOLOGY

It is thought that genetically susceptible individuals ≤15 years of age who have lived in a high-risk area for at least 2 years and were exposed to a crucial environmental agent are at risk for developing MS. Interestingly, an individual who migrates from a low- to a high-risk area prior to the age of 15 years acquires the same chance of developing MS as those who live in a high-risk area all their lives.  

If the move is made from a high- to a low-risk area, the individual retains the high risk if the move is made after the age of 15 years but acquires the lower risk if the move is made prior to this age. Smoking cigarettes has been associated with both an increased risk of developing MS and with more severe progression of disability.  

Viral or bacterial infections may be an important environmental cause of MS. Although no clear association has been identified, infections might cause either a direct attack on myelin and the oligodendrocyte, or stimulation of an autoimmune response leading to demyelination. Evidence to support a viral etiology includes increased immunoglobulin G (IgG) synthesis in the CNS, increased antibody titers to certain viruses, and epidemiologic studies that indicate a childhood exposure factor, suggesting that "viral" infections may precipitate exacerbations. In addition, viruses have been shown to cause diseases with prolonged incubation periods, myelin destruction, and a relapsing-remitting course in both humans and experimental animal models.  

Although numerous viruses have been proposed as associated with MS, the greatest evidence is for Epstein-Barr virus (EBV). Antibody titers to Epstein-Barr nuclear antigen (EBNA) complex are higher in MS patients vs controls, especially if blood is collected ≥5 years before onset. These titers increase over time in MS patients vs controls (controls are unchanged), and a 4-fold increase in EBNA titers over time results in a 3-fold increased risk of developing MS (almost 18-fold increase in those with first samples before age 20). Interestingly, one paper notes individuals positive for HLA DRB1*1501 have a 24-fold increased risk of developing MS when they also have antibodies to certain epitopes within EBNA-1 compared with others. This is consistent with a genetic-environmental interaction. In addition, anti-EBNA titers have been associated with relapsing-remitting MS (RRMS), conversion of clinically isolated syndrome (CIS) to RRMS, and with magnetic resonance imaging (MRI) measures such as gadolinium-enhancing lesions, change in T2 lesion volume (r = 0.27; P = 0.044), and Expanded Disability Status Scale (EDSS) score (r = 0.3; P = 0.035). Zivadinov et al. also found anti-EBNA and anti-vascular cell adhesion (VCA) titers associated with gray matter atrophy in MS. While Serafini et al. have claimed to identify evidence of abortive infection in a significant number of MS patients, others have not been able to replicate these findings. The majority of the data would lead to a conclusion that exposure to EBV is somehow associated with developing MS, but does not support the concept of an active or aborting EBV infection directly causing MS.  

The familial recurrence rate of MS is approximately 5%, with siblings being the most commonly reported relationship, and a concordance rate among monozygotic twins of approximately 25%. This is consistent with the idea that an environmental agent is important in the etiology of MS, but also suggests a role for one or more genes. Genes that lie within the major histocompatibility complex (MHC), which is located on the sixth chromosome in humans, have been linked to MS. Recent data show a significant association of risk with mutations in the IL-2a and IL-7a receptor genes. African Americans are significantly less likely to be diagnosed with MS compared with whites, though there is emerging evidence that they are more likely to have a severe disease course and respond less well to interferon therapy. A locus on chromosome 1 may be associated with increased susceptibility in African Americans.  

PATHOPHYSIOLOGY

The basic physiologic derangement in MS is the stripping of the myelin sheath surrounding CNS axons. This activity is associated with an inflammatory, perivenular infiltrate consisting of T and B lymphocytes, macrophages, antibodies, and complement. Demyelination renders axons susceptible to damage, which becomes irreversible when they are severed. Irreversible axonal damage correlates with disability and can be visualized as hypointense lesions, or "black holes," on T1-weighted MRI.  

It is now well accepted that MS lesions are heterogeneous, which may be in part due to differences in the stage of evolution of the lesions over time, differences in underlying immunopathogenesis, or a combination of the two. Briefly stated, acute lesions show demyelination and axonal destruction with lymphocytic activity consistent with an inflammatory state. In contrast, more chronic lesions display less inflammatory lymphocytes with active remyelination. Although traditional descriptions have focused on the white matter as the sole location of MS lesions, more recent studies have clearly identified cortical and subcortical gray matter lesions both pathologically and radiographically. In addition, a subset of patients with progressive MS are noted to have abnormalities consistent with B-cell follicles in the meninges. Just as the full dimensions of the neuropathology are uncertain, so is the pathogenesis of the MS lesion. There is substantial evidence, however, to suggest it is an autoimmune process directed against myelin and oligodendrocytes, the cells that make myelin in the CNS. Figure 64–1. A new concept of T-cell entry into the CNS suggests that the initial lymphocyte invasion in MS may proceed through the ventricles, towards the choroid plexus along a CCL 20 gradient that attracts activated Th17 cells. The actual mediator of myelin and axonal destruction has not been established, but may reflect a combination of macrophages, antibodies, destructive cytokines, and reactive oxygen intermediates. The exact trigger for the activation of the T cells in the periphery remains unclear, but the T cells in MS patients recognize myelin basic protein (MBP), proteolipid protein, myelin oligodendrocyte glycoprotein, and myelin-associated glycoprotein. T-helper subtypes can be either pathogenic or protective in MS. Furthermore, theory holds that certain T-cell subsets are not terminally differentiated, but instead engender a level of plasticity that allows for their conversion from pathogenic to protective and vice versa under certain conditions. In patients with stable or mild disease, increased numbers of cells are found that express messenger RNA (mRNA) for transforming growth factor-β (TGF-β) and interleukin-10 (IL-10) compared with patients with severe disease. Conversely, a reduction in the number of T-regulatory (Treg) cells, which exhibit suppressor activity, is associated with active MS and can be found in patients with progressive disease. It should be noted, however, that Treg ratios do not always correlate with disease activity. Of note, there is experimental evidence that associates high 25-hydroxyvitamin D levels with improved Treg function, favoring the Th2 phenotype in the Th1/Th2 balance. Finally, the significance of one of the immunological hallmarks of MS, the intrathecal synthesis of multiple clones of immunoglobulins, remains unclear. The antigen(s) against which these immunoglobulins are directed remain unknown, but do not appear to include common CNS myelin antigens. The complex interplay of a variety of cells, antibodies, and cytokines remains to be elucidated.
Multiple Sclerosis

CHAPTER 64

CLINICAL PRESENTATION OF MULTIPLE SCLEROSIS

General

- Most patients with multiple sclerosis present with nonspecific complaints. Many have problems with their vision or paresthesias.

Primary Symptoms/Signs

- Visual complaints/optic neuritis
- Gait problems and falls
- Paresthesias
- Pain
- Spasticity
- Weakness
- Ataxia
- Speech difficulty
- Psychological changes
- Cognitive changes
- Fatigue
- Bowel/bladder dysfunction
- Sexual dysfunction
- Tremor
Laboratory Tests
- MS is a diagnosis of exclusion
- Magnetic resonance imaging
- Cerebrospinal fluid studies
- Evoked potentials

Secondary Symptoms
- Recurrent urinary tract infections
- Urinary calculi
- Decubiti and osteomyelitis
- Osteoporosis
- Respiratory infections
- Poor nutrition
- Depression

Tertiary Symptoms
- Financial problems
- Personal/social problems
- Vocational problems
- Emotional problems

CLINICAL PRESENTATION AND COURSE OF ILLNESS

The clinical presentation of MS is extremely variable among patients and typically varies over time in a given patient. The signs and symptoms of MS can be divided into three categories. Primary symptoms are a direct consequence of conduction disturbances produced by demyelination and axonal damage and reflect the area

FIGURE 64-2. Upon interaction with an antigen-laden APC and specific cytokines, the innate T-cells undergo differentiation into a few lineages (subtypes). Four subtypes significant for MS pathophysiology are illustrated here (Th1, Th2, Th17, Treg). Th1 and Th17 are pro-inflammatory, Th2 is anti-inflammatory, and Treg is regulatory. Th1 and Th2 are mutually suppressive and are relatively stable differentiated subtypes. In contrast, Th17 and Treg subtypes are recently found to exhibit “plasticity.” In other words, they can undergo phenotypic conversion to another T-cell subtype (Th1 or Th2) in the presence of specific cytokine conditions. This plasticity of Th17 and Treg is the immunologic basis for development of therapeutic agents to favor the production of suitable Th subtypes for combating microbial invasion and also concurrently achieving neurocellular recovery after an infection.27 (APC, antigen presenting cell.)

CLINICAL CONTROVERSY

A small but significant number of patients have been identified who have not had clear MS symptoms, but MRI scans, typically done for purposes other than to look for signs of MS, have identified what appear to be typical lesions consistent with MS. Patients may then have further changes on MRI scans, again with no clinical signs. Similarly, a significant percentage of patients with established MS will have MRI changes unassociated with new clinical signs. It is unclear whether MRI changes in isolation should trigger a clinician to begin or alter therapy.
of the brain or spinal cord that is damaged. Secondary symptoms are complications resulting from primary symptoms. For example, urinary retention, a primary symptom, can lead to frequent urinary tract infections, a secondary symptom. Tertiary symptoms relate to the effect of the disease on the patient’s everyday life.30

The clinical course of MS is classified into four categories.31 At the onset of symptoms, about 85% of patients have attacks—new symptoms lasting at least 24 hours and separated from other new symptoms by at least 30 days—followed by remissions (complete or incomplete). Attacks frequently are referred to as relapses or exacerbations, and the first attack is called a clinically isolated syndrome. This course is called relapsing-remitting MS. During the RRMS phase, there is a correlation between new brain MRI lesions and clinical attacks, but typically there are many more new MRI lesions than new clinical symptoms. In RRMS patients, attack frequency tends to decrease over time and becomes independent of the development of progressive disabilities.32 Neurologic recovery following an acute exacerbation is often quite good early in the disease course, but following repeated relapses, recovery tends to be less complete. In addition, there is a new concept of a radiologically isolated syndrome (RIS), referring to individuals who have clinical scenarios not typical of MS, yet obtain MRI scans for other reasons (e.g., headache) and have radiological signs suggestive of MS. Some percentage of these patients convert to typical MS over time,33 although when to start treatment remains unclear.

Up to 10% to 20% of RRMS patients have a benign course, characterized by few relapses, often sensory, with minimal disability accruing over time. Most RRMS patients eventually enter a progressive phase in which attacks and remissions generally are difficult to identify. This is referred to as secondary-progressive MS (SPMS). Disability tends to accumulate more significantly during this phase of the illness. New brain MRI lesions, especially those seen only after the injection of contrast material, are less common, and brain atrophy and T1 holes increase.34

Approximately 15% of patients never have acute attacks and remissions but have progressive disease from the outset, known as primary-progressive MS (PPMS). These patients will have symptoms, especially spastic paraparesis, that may worsen rapidly or relatively slowly over time, and they accrue progressively more disability. Patients with PPMS are diagnosed at a later age, and the number of males is roughly equal to that of females. In general, PPMS patients tend to have a worse prognosis than those who present initially with RRMS, although more recent data suggest progression is variable.35 Many clinical trials have suggested that a significant portion of patients with PPMS do not receive benefit from studied therapies. However, a recent article using rituximab suggests a subgroup of PPMS patients who are less than 51 years of age and have at least one gadolinium-enhancing lesion may benefit from this therapy.36 Finally, a small percentage of patients may have a mixture of both progression and relapses, referred to as progressive-relapsing MS (PRMS). These are generally treated as relapsing patients.

Progression of the illness throughout the lifetime of the individual can be measured in many ways. The most widely used clinical rating scale in MS is the EDSS, which uses a numerical value ranging from 0 (no disability) to 10 (death from MS) to evaluate several neurologic functions.37 The limitations of this scale are the relative insensitivity to clinical changes not involving impairment of gait and ambulation, such as changes in cognition, fatigue, and affect. Other tools, such as the Multiple Sclerosis Functional Composite (MSFC), are being evaluated for possible increased sensitivity and utility in describing changes in MS-related disability over time.38 Increasingly, MRI is being used as an index of both disease activity and progression.39 Specifically, the appearance of new lesions or changes in lesion number, size, and volume are being used as outcome measures in research studies. Optical coherence tomography measures the retinal neural fiber layer thickness, and may also be a measurable sign of pathological progression over time.39

The unpredictable nature of MS makes it impossible to anticipate when an exacerbation will occur. However, certain factors may aggravate symptoms or lead to an acute attack (new episode of demyelination), including infections, heat (including fever), sleep deprivation, stress, malnutrition, anemia, concurrent organ dysfunction, exertion, and childbirth. Interestingly, many patients experience a significant reduction in acute relapses during the third trimester of pregnancy, followed by a relative increase postpartum.40

Multiple sclerosis usually does not directly diminish life expectancy. The development of secondary complications such as pneumonia or sepsis (secondary to aspiration of mouth contents with swallowing difficulties, decubitus ulcers, or urinary tract infections) or rapid progression of primary lesions affecting respiratory function can lead to a shorter than expected life span. Most of this decrease in life span is seen in patients with rapidly progressive disease. Suicide rates as high as 7 times that expected in the general population have been reported.41 Clinical and demographic factors used to predict prognosis of MS are listed in Table 64–1.42 Several MRI features also have been shown to correlate with progression of disease (see below).43–46

### DIAGNOSIS

Multiple sclerosis is a diagnosis of exclusion; symptoms frequently can be attributed to other neurologic diseases, just as many syndromes can mimic MS. Some patients may have typical symptoms consistent with classic CIS, whereas many others may have symptoms that are more vague. The diagnosis remains primarily a clinical one that requires the demonstration of “lesions separated in space and time,” referring to the occurrence of at least two episodes of neurologic disturbance reflecting distinct sites of damage in the CNS that cannot be explained by another mechanism.43 An international panel of MS experts was convened in 2000 to reevaluate current diagnostic criteria and to incorporate new data. The result of this panel’s work is the McDonald criteria,45 which allow brain MRI lesions, cerebrospinal fluid (CSF) abnormalities, and visual-evoked potential (VEP) studies to substitute for clinical lesions in defining “separated in space and time.” A recent reevaluation of the McDonald criteria has simplified the use of these laboratory studies.44 In the new scheme, diagnostic categories are MS, possible MS (for those individuals at high risk of developing MS), and not MS. The new criteria allow for earlier diagnosis.45 Newer, simpler MRI criteria defining dissemination in time and space may be somewhat more sensitive and equally specific.46–48 A consensus panel of the American Association of Neurology endorses the utility of MRI for diagnostic purpose,47 and the U.S. Food and Drug Administration (FDA) has approved several of the immunotherapies to be used after a single attack of demyelination in the context of an appropriately abnormal brain MRI.
LABORATORY STUDIES

To date, there are no tests specific for MS. Evidence provided by MRI of the brain and spine, CSF evaluation, and evoked potentials, used in conjunction with the physical examination and history, aids in establishing the diagnosis of MS.

Imaging Studies

MRI produces images of the brain and spine that reflect damage in the CNS that is characteristic of MS plaques in multiple forms, for instance, in the periventricular white matter areas of the brain, as well as more generalized abnormalities such as brain atrophy. MRI is the preferred technique and is much more sensitive than computed tomography. It is useful for establishing diagnosis and prognosis. Patients with a single, typical attack of demyelination (possible MS or CIS, e.g., optic neuritis) and three or more T2-weighted lesions on the brain MRI have an almost 90% likelihood of developing a second attack (clinically definite MS) over 15 years. Optic neuritis is a common first symptom of MS and is indicative of a lesion or lesions localizing on the optic nerve. In contrast, similar individuals with normal brain MRIs have only a 19% likelihood of developing MS over 15 years. Total volume of T2-weighted lesions (called T burden of disease) at the onset of CIS also appears to correlate with the development of disability. Lesions that enhance after injection of the contrast material gadolinium indicate new lesions and disruption of the blood-brain barrier and are associated with early conversion to MS in CIS/possible MS patients, but do not correlate well over time with progression of disability. Brain atrophy, even early in the course of the illness, probably correlates better with progression of disability.

CSF Evaluation

In MS patients, CNS synthesis of IgG is increased, whereas serum IgG levels are normal. IgG synthesis rate, or the so-called IgG index, is used in conjunction with the physical examination and history, aids in establishing the diagnosis of MS. One potential algorithm for the immunotherapy of RRMS is shown in Figure 64–3.

Evoked Potentials

Evoked potentials may be helpful in establishing areas of demyelination that are clinically silent. Slowed conduction of visual, brainstem, and somatosensory potentials can be identified, although the sensitivity and specificity of these tests seem to be somewhat less than that seen with MRI or CSF evaluation. Newer diagnostic criteria allow only for the use of VEPs to aid in formal diagnosis.

Blood Studies

A recent report has suggested that in CIS patients with abnormal brain MRIs and abnormal CSF consistent with MS, presence or absence of antimyelin antibodies in serum may be helpful in defining prognosis for further events consistent with clinically definite MS. The utility of this test, if any, remains to be defined.

DIFFERENTIAL DIAGNOSIS

A number of disorders can mimic MS. Thus, most patients are screened with blood tests for rheumatologic, collagen-vascular, infectious, and sometimes inherited metabolic diseases. Magnetic resonance imaging may rule out tumors and cerebral spongiosis. The use of MRI has led to evaluations for MS in many patients with little or no clinical history consistent with MS; while some of these patients may have MRI scans suggestive of MS (so-called RIS), most of these patients have non-specific MRI scans with identifiable causes for their scan abnormalities, including age greater than 50 years, hypertension, and migraine. There are many causes of non-specific lesions seen in the subcortical white matter on a brain MRI, and use of established criteria for distinguishing MS lesions from other etiologies enhances diagnostic accuracy. Electromyography may help in diagnosing amyotrophic lateral sclerosis and neuropathies.

TREATMENT

Treatment of MS falls into three broad categories: symptomatic therapy, treatment of acute attacks, and disease-modifying therapies (DMTs) to alter the natural course of the disease. Symptomatic management of the disease is of utmost importance to maintain the patient’s quality of life. Treatment of acute attacks will shorten the duration and possibly decrease the severity of the attack. Disease-modifying therapies that alter the course of the illness are most important to diminish progressive disability over time.

A number of different treatment modalities have been studied in the last 30 years, but many older trials had flawed designs. There are no universally accepted treatment algorithms, and treatments vary among clinicians and centers. Perhaps more importantly, treatment decisions frequently are based on the wishes and goals of individual patients. One potential algorithm for the immunotherapy of RRMS is shown in Figure 64–3.

CLINICAL CONTROVERSY

When patients initially show signs of RRMS, many practitioners begin treatment with IFN-β or glatiramer acetate (ABC-R medications). However, it is controversial which medication to use, and when to start. Most data support minimal, if any, differences in efficacy among the ABC-R medications. The role of natalizumab remains unclear, but under 10% of natalizumab prescriptions have been for patients who use the ABC-R medications. The introduction of fingolimod further complicates the issue. Most practitioners assist newly diagnosed patients in making the decision of which medication best fits their lifestyle and offers the maximum efficacy. In patients with severe depression, interferon therapy is contraindicated, and patients are encouraged to use glatiramer acetate.

Mild acute exacerbations that do not produce functional decline may not require treatment. When functional ability is affected, the standard intervention is intravenous injection of high-dose corticosteroids. The American Academy of Neurology recommends that if treatment with steroids is warranted, it is best to use intravenous methylprednisolone. The mechanism of action for corticosteroids in MS is unknown, but it is speculated that steroids improve recovery by decreasing edema in the area of demyelination.
Neurological symptoms suggestive of multiple sclerosis (MS)

- **Not MS**
  - Other Rx
  - No Rx
  - Treat
  - Evaluate as necessary
  - Monitor clinically & radiographically

- **Possible MS**
  - RIS
  - Other Rx
  - No Rx
  - CIS low risk of further attacks by MRI ± LP
  - CIS high risk of further attacks by MRI ± LP
  - More MRI lesions and/or clinical relapse
  - Treat
  - Evaluate as necessary
  - Watch & wait

- **RRMS**
  - Average risk of disability, consider primary Rx with interferon, glatiramer acetate, or fingolimod unless pregnant or other reason not to.

- **PPMS**
  - No FDA approved Rx. Consider experimental Rx or rituximab if <51 years old and/or enhancing lesions on MRI.

- **CIS**
  - Low risk of further attacks by MRI ± LP
  - High risk of further attacks by MRI ± LP
  - Monitored clinically & radiographically
  - Other Rx
  - No Rx
  - Treat
  - Evaluate as necessary
  - Watch & wait

- **Conversion to SPMS**
  - Still relapsing within last year and never on interferon and/or enhancing lesions are present.
  - No relapses for several years and no enhancing lesions.
  - No recent relapses, no enhancing lesions, and failed interferon, and not young or short disease duration.

- **Patient obtains MRI for reasons other than MS symptoms**
  - Not MS
  - Possible MS
  - RRMS
  - PPMS

- **Does well clinically & radiographically**
  - Continue medication

- **Does poorly clinically and/or radiographically still relapsing**
  - If on interferon, and:
    - Change to fingolimod
    - Change to glatiramer acetate
    - Change to natalizumab
    - Add intermittent IV MP
    - Change rituximab
    - Change to mycophenylate or IVIG

- **If high titer Ab ⊕, must consider:**
  - Change to glatiramer acetate
  - Change to fingolimod
  - Change to natalizumab
  - Change to rituximab
  - Change to mycophenylate or IVIG

- **If Ab ⊕, continue Rx or consider:**
  - Change to fingolimod
  - Change to glatiramer acetate
  - Change to interferon
  - Change to rituximab
  - Change to experimental Rx

- **If Ab ⊕, continue Rx or consider:**
  - Change to fingolimod
  - Change to glatiramer acetate
  - Change to interferon
  - Change to rituximab
  - Change to experimental Rx

- **If Ab ⊕, continue Rx or consider:**
  - Change to fingolimod
  - Change to glatiramer acetate
  - Change to interferon
  - Change to rituximab
  - Change to experimental Rx

FIGURE 64-3. An algorithm for management of relapsing-remitting multiple sclerosis. (ABC-R, interferon $\beta_1$, [Avonex], interferon $\beta_2b$ [Betaseron], glatiramer acetate [Copaxone], and interferon $\beta_1a$ [Rebif]; IVIg, intravenous immunoglobulin.)
Intravenous methylprednisolone has been shown to shorten the duration of acute exacerbations, and it may delay repeat attacks for up to 2 years after optic neuritis, although it has not been shown definitively to affect the progression of disease. More recently, many practitioners are using high doses of oral methylprednisolone, especially mixing the lyophilized powder in flavored drinks such as smoothies, but there are no comparative data to define this as an equivalent way to deliver the medication.

Methylprednisolone doses can range from 500 to 1,000 mg/day, given intravenously. The duration of therapy is variable and can range from 3 to (rarely) 10 days, depending on clinical response. If improvement occurs, it usually begins to be seen after 3 to 5 days. Short-term use of this nature is often accompanied by sleep disturbance, a metallic taste, and, rarely, gastrointestinal upset. Patients with diabetes mellitus or a predilection to diabetes mellitus may have significant elevations of blood sugar, requiring the use of insulin. Longer durations of intravenous methylprednisolone therapy are associated with acute and fungal infections, mood alteration, and, rarely, gastrointestinal hemorrhage (especially if used in hospitalized patients or those taking aspirin concurrently). If methylprednisolone is not available, equipotent doses of dexamethasone have been used as a substitute, although not well supported in the literature.

A very small number of patients have more severe attacks, manifested by hemiplegia, paraplegia, or quadriplegia. If these patients fail to improve with aggressive steroid therapy, plasma exchange every other day for seven treatments can be beneficial for approximately 40% of patients.

### DISEASE-MODIFYING THERAPY

#### Interferon $\beta_{1b}$ and Interferon $\beta_{1a}$

Interferon (IFN)-$\beta_{1b}$ (Betaseron) was the first agent proven to favorably alter the natural course of the illness. In Table 64–2, disease-modifying therapies are listed with evidenced-based recommendations from the American Academy of Neurology. Although the exact mechanism of action is unknown, IFN-$\beta_{1a}$’s effect in MS may be caused by its immunomodulating properties, including the ability to augment suppressor cell function and reduce IFN-$\gamma$ secretion by activated lymphocytes, its macrophage-activating effect, and its ability to downregulate the expression of IFN-$\gamma$-induced class II MHC gene products on antigen-presenting glial cells. Interferon also suppresses T-cell proliferation and may decrease blood–brain barrier permeability. IFN-$\beta$ also increases the production of regulatory CD56 (bright) natural killer cells and Treg cells. In general, all interferons exert these actions in the periphery and at the blood–brain barrier level. Interferons work at the blood–brain barrier level by decreasing matrix metalloproteinases.

Interferon $\beta_{1a}$ is a nonglycosylated synthetic analog of recombinant IFN-$\beta$ and is produced in *Escherichia coli*. Interferon $\beta_{1a}$ is administered subcutaneously every other day at a dose of 250 mcg (8 million international units). Clinical trials have demonstrated that at these doses, IFN-$\beta_{1a}$ significantly reduces annual relapse rate and MRI burden of disease compared with placebo. With respect to clinical disability, however, no significant differences were noted between the interferon- and placebo-treated groups. Betaseron is packaged in partially premixed syringes with a new formulation that does not require refrigeration and can be used with an autoinjector. Betaseron costs approximately $19,632 per year. In 2009, an additional interferon product was introduced into the market under the trade name Extavia. Extavia is the same medicinal product as Betaseron.

Interferon $\beta_{1a}$ (Avonex and Rebif) is a natural-sequence glycosylated interferon produced in Chinese hamster ovary cells. Avonex is given as 30 mcg (6 million international units) intramuscularly once weekly. The prefilled syringes (33 mcg/0.5 mL, 4 per package) should be refrigerated, but can be kept at room temperature for 30 days. Avonex costs approximately $18,360 per year. Rebif is made in a very similar fashion as Avonex but given as either 22 or 44 mcg (0.5 mL) subcutaneously 3 times weekly. It is supplied in a 0.5-mL prefilled syringe with an autoinjector and costs approximately $21,163 per year. Rebif should also be kept refrigerated, but it is stable at room temperature for 30 days. A new formulation may have lower immunogenicity and a slightly better side-effect profile.

When given 30 mcg intramuscularly once weekly for 2 years, patients receiving IFN-$\beta_{1a}$ (Avonex) demonstrated, compared with placebo, statistically significant reductions in annual relapse rate (by approximately one-third) as well as disease progression, which was defined as a confirmed decrease of 1 point on the EDSS. Disease progression also was assessed by MRI studies, and patients receiving active drug had significantly fewer new enhancing lesions compared with placebo-treated patients. Similar results were seen with higher dose (44 mcg), more frequent administration (3 times weekly), and subcutaneous injection of IFN-$\beta_{1a}$ (Rebif). Other
studies reveal significant effects on slowing brain atrophy\textsuperscript{58} and the progression of cognitive decline\textsuperscript{59} in patients treated with Avonex. Taken together, these observations show that IFN-\(\beta\) possesses significant disease-modifying activity.

Side effects are similar with all the interferons. Baseline complete blood counts, platelet determinations, and liver function tests should be documented before starting therapy, at 1 month, then every 3 months for 1 year, and every 6 months thereafter. Small percentages of patients develop depressed cell counts and liver enzyme elevations that are usually transient and respond to discontinuation of therapy. Rare patients have developed true liver failure requiring liver transplant, and the package inserts for interferon \(\beta\) products have been altered, reflecting this risk. The most common adverse effects include injection-site redness, swelling, and, rarely, necrosis, as well as flu-like symptoms (e.g., fever, chills, myalgias). These symptoms can be mild or severe and are seen in most patients. The flu-like side effects typically occur for up to 24 hours after injection and typically abate within 1 to 3 months after starting the injections, but they persist in some patients. Injection-site reactions probably are worse with IFN-\(\beta_{1a}\) can occur at any time, and can be lessened by using appropriate injection technique, including site rotation (thighs and buttocks), hydrocortisone cream, applying ice before and after the injection, or use of an autoinjector. Injecting the medications at body temperature (place under armpits) will decrease injection-site pain. Nonsteroidal antiinflammatory agents or acetaminophen taken before and at regular intervals for 24 hours after administration may alleviate the flu-like symptoms. Initiation of one-quarter or one-half the standard dose, and then increasing to full dosage over 1 to 2 months, also may be beneficial in reducing flu-like side effects.\textsuperscript{60} Some authors suggest that, because of the transient immune activation that can occur following the introduction of IFN-\(\beta\), a short burst of oral prednisone can alleviate some adverse effects.\textsuperscript{61}

Less commonly reported side effects include shortness of breath, tachycardia, thyroid dysfunction, and depression. Clinicians must monitor patients carefully for signs of depression and treat accordingly. Although depression is a common finding in MS patients, all the interferons, especially IFN-\(\beta_{1a}\), can produce depressive symptoms. Patients who develop depression should be monitored closely because of the risk for suicide. Other side effects usually are transient. Most patients will not feel better or have improvement in symptoms when taking interferons, and many will experience side effects; thus compliance can become a major issue. Finally, safety data on IFN-\(\beta\) in pregnancy and lactation are lacking. Abortifacient activity in primates has been noted, and until adequate safety data are available, women should be counseled as to appropriate contraception while using these products.

Although the adverse-effect profile of IFN-\(\beta_{1a}\) resembles that of IFN-\(\beta_{1b}\), intramuscular IFN-\(\beta_{1b}\) (Avonex) may hold several advantages, including fewer local injection-site reactions and once-weekly administration versus subcutaneous injection every other day (or 3 days per week with Rebif).

### Glatiramer Acetate (Copaxone)

Glatiramer acetate (Copaxone, formerly known as copolymer-1) is a synthetic polypeptide consisting of l-alanine, l-glutamic acid, l-lysine, and l-tyrosine. Although the precise mechanism of action of this compound is unknown, glatiramer acetate appears to mimic the antigenic properties of MBP.\textsuperscript{41} This agent also may act by directly binding to MHC class II receptors and inhibiting binding of MBP peptides to T-cell receptor complexes.\textsuperscript{41} Glatiramer acetate has demonstrated that it induces Th2 (antiinflammatory) lymphocytes in experimental allergic encephalomyelitis.\textsuperscript{41} This is thought to contribute to “bystander” suppression at the site of the MS lesion and thereby reduce inflammation, demyelination, and axonal damage.\textsuperscript{41} Glatiramer acetate also may suppress T-cell activation, and recent studies suggest it may be associated with a neuroprotective effect by inducing brain-derived neurotrophic factor.\textsuperscript{52}

Given as a daily 20-mg subcutaneous dose, glatiramer acetate appears to have a relatively mild adverse effect profile. Mild pain and pruritus at the injection site are the most frequent patient complaints. Approximately 10% of patients experience a one-time transient reaction consisting of chest tightness, flushing, and dyspnea beginning several minutes after injection and lasting usually no longer than 20 minutes. If patients have no history or evidence of coronary artery disease, they may be assured these reactions are almost always self-limited and benign. Several adverse effects that have been associated with the interferons, including flu-like symptoms and depression, do not appear to be provoked by glatiramer acetate. Multicenter trials with glatiramer acetate have demonstrated significant reductions in mean annual relapse rate (approximately 29%) that are comparable with the interferons.\textsuperscript{55} An extension trial, completed after the original, pivotal 2-year study, suggests that glatiramer acetate may slow the progression of disability in patients with RRMS.\textsuperscript{55} Glatiramer acetate also slows development of \(T_\text{h}1\) holes on brain MRIs,\textsuperscript{48} and long-term uncontrolled data show that it remains safe and effective for individuals who continue to take it over 10 years.\textsuperscript{54} The annual cost of glatiramer acetate is approximately $19,749 (20 mg/mL in 30 prefilled syringes). The product is stored in the refrigerator but can be kept at room temperature for up to 1 week.

#### CLINICAL CONTROVERSY

Because of the potential for progressive multifocal leukoencephalopathy (PML), controversy surrounds the proper selection of patients for natalizumab therapy. With the apparent superior efficacy of natalizumab compared to other disease-modifying therapies, many clinicians use natalizumab as a primary agent in selected individuals with RRMS who are identified with poor prognostic signs such as multiple early relapses, severe relapses with incomplete remission, and MRI markers of poor prognosis, such as high burden of disease on \(T_\text{1b}\) and \(T_\text{2}\) images, or early signs of atrophy. Whether to restrict the use of natalizumab to a maximum number of months, or alter the dosing, in an effort to limit the risk of PML, remains unclear. Prior exposure to chemotherapy appears to increase risk of PML. The advent of a serology study for JC Virus exposure may alter clinicians’ willingness to prescribe natalizumab as a first line agent or alter the duration that they prescribe it.

### Natalizumab (Tysabri)

Natalizumab is a partially humanized monoclonal antibody directed at the cell surface adhesion molecule \(\alpha_4\beta_1\)-integrin (also known as very-late antigen 1, VLA-1). Natalizumab works by attaching to VLA-1 and blocking its interaction with its ligand on CNS endothelium vascular cell adhesion molecule (VCAM)-1. Thus, activated lymphocytes are denied entry past the blood—brain barrier. In a phase II study, compared to placebo, natalizumab significantly reduced the number of new gadolinium-enhancing lesions by more than 90%, and diminished relapses as well.\textsuperscript{45} In a 2-year phase III trial (A Randomized, Placebo-Controlled Trial of Natalizumab for Relapsing Multiple Sclerosis [AFFIRM]), compared to placebo, annual relapse rate was reduced by more than 60%, gadolinium-enhancing lesions were lessened by more than 90%, and progression of disability was significantly delayed.\textsuperscript{46} In a separate 2-year, phase III trial (The Safety and Efficacy of Natalizumab in Combination with
Interferon Beta-1a in Patients with Relapsing Remitting Multiple Sclerosis (SENTINEL) in patients already taking IFN-β (Avonex), those who had natalizumab added to IFN-β had a relapse rate reduction of more than 50% and gadolinium-enhancing lesion reduction of 84% compared to patients who continued with IFN-β alone. In these trials, natalizumab was injected intravenously every 4 weeks and was relatively well tolerated, although approximately 1% of patients developed infusion reactions, and 6% developed neutralizing antibodies that diminished the efficacy of the drug.

On November 23, 2004, the FDA approved natalizumab, with the stipulation that the studies would continue, for use in relapsing MS in patients with inadequate response or intolerance to other MS therapies. In February 2005, Biogen and Elan voluntarily removed natalizumab from the market after receiving reports of two patients (one patient from the SENTINEL trial, and one patient in a Crohn’s disease study), who both died after developing progressive multifocal leukoencephalopathy (PML), a rare brain infection most commonly seen in patients infected with human immunodeficiency virus. One other patient who developed PML in the SENTINEL trial survived. Further safety analysis did not identify other cases, and on March 9, 2006, an FDA panel reviewing the data suggested reapproval of natalizumab for use in relapsing patients who would be required to be placed in an ongoing safety registry (TOUCH). On June 5, 2006, the FDA reapproved use of natalizumab in the United States, with a black-box warning about PML. Since that time, over 71,000 patients around the world (roughly 50% in the United States) have been exposed to natalizumab for treatment of MS. As of September 2010, 68 cases of PML have been identified, all in patients using the medication for 12 months or longer. The incidence for developing PML is 1 in 1,000, though it tends to increase the longer a patient is on the drug. Plasma exchange (PLEX) has been utilized to help clear the drug more rapidly from the blood of affected patients.

An acute syndrome referred to as immune reconstitution inflammatory syndrome has been associated with acute neurologic disorders, including, rarely, bradyarrhythmia or atrioventricular block, infections, and the patient must be observed for 6 hours, although the monitoring setting may be individualized. The degree to which fingolimod’s oral delivery may alter the likelihood of a patient using, or continuing to use, a self-injectable medication remains to be seen.

Fingolimod (Gilenya)

Approved September 21, 2010, fingolimod is the first oral DMT approved for other purposes, such as rituximab and mycophenolate. When to incorporate off-label uses of medications remains a controversy.

Mitoxantrone

Mitoxantrone (Novantrone), a member of the anthracycline family, is approved by the FDA for reducing neurologic disability and the frequency of clinical relapses in patients with SPMS (chronic, PRMS, or worsening RRMS). The MRI outcomes, however, were not as robust as those typically seen in the trials of relapsing patients alone. Mitoxantrone is administered as a brief (5- to 15-minute) intravenous infusion with FDA approval for use in SPMS, there was no substudy documenting slowing of progression specifically in this subgroup of patients. Thus, support for use of mitoxantrone in this context is less strong. The average wholesale cost of mitoxantrone is approximately $1,982 (average male) or $1,586 (average female) per infusion and will vary based on the patient’s body surface area. Nursing, pharmacy, and technical fees must also be added to this estimate.

Mitoxantrone

Approved September 23, 2004, mitoxantrone is indicated for the treatment of acute leukemia and refractory anemia. Mitoxantrone is a member of the anthracenedione family and has been approved by the FDA for reducing neurologic disability and the frequency of clinical relapses in patients with SPMS. Despite encouraging results from well-conducted clinical trials, several relevant issues remain. The most important question in the use of the DMTs is when to begin therapy. The Medical Advisory Board of the National Multiple Sclerosis Society has adopted recommendations regarding the use of the current MS DMTs (Table 64–3).

Decisions about the use of any medication rest on determination of the severity of the illness, the efficacy of the medication, and the side effects and costs related to the therapy. Clearly,
these drugs slow the course of the illness but do not suppress it completely, and in some individuals, there is no apparent benefit. There is now, however, overwhelming evidence that the vast majority of untreated patients will have progressive disease over time. Pathologic data clearly show that even in acute lesions there is significant axonal damage that is essentially irreversible. MRI data show that 80% to 90% of all new enhancing lesions are asymptomatic, suggesting that a “quiet” clinical course does not necessarily mean there is not ongoing disease activity that ultimately will be reflected in cognitive problems and progressive spastic paraparesis.

Furthermore, it is now known that very early therapy is effective. In patients with CIS and two or more T2 lesions on brain MRI (i.e., at high risk for developing clinically definite MS), placebo-controlled studies with all three of the interferon agents and glatiramer acetate have shown significant delay in a second attack and positive outcomes on a variety of MRI measures (BENEFIT = Betaseron in Newly Emerging Multiple Sclerosis for Initial Treatment; CHAMPS = Controlled High Risk Subjects Avonex Multiple Sclerosis Prevention Study; and ETOMS = Early Treatment of Multiple Sclerosis). Thus, very early therapy is potentially warranted, and IFN-β1a, IFN-β1b (Avonex), and glatiramer acetate are approved by the FDA for use after CIS in those patients with abnormal MRIs consistent with demyelination, suggestive of high risk of further demyelinating events. The National Multiple Sclerosis Society recommends that patients with relapsing disease should be placed on Avonex, Betaseron (or Extavia), Copaxone, or Rebif (ABC-R) therapy immediately after the diagnosis.

A second major issue is which drug to use in which patient. There has not been a single, randomized study comparing all four ABC-R drugs with one another in a similar patient population at the same time. The pivotal placebo-controlled trials produced results that were more similar than different when comparing across trials, including a nearly identical one-third reduction in relapse rate for all four drugs over 2 years. A small number of studies have suggested higher dose, more frequent administration of interferon may be more efficacious than lower dose, less frequent administration, but these differences appear modest. Other studies argue against this, and recent studies note no significant difference in outcomes between standard and double dose IFN-β1b and glatiramer acetate, and no difference between IFN-β1b (Rebit) and glatiramer acetate. A concern with all three interferon products that further muddies our understanding of the clinical differences between the interferon products is the development of neutralizing antibodies. In clinical trials, 30% to 40% of patients receiving IFN-β1b, developed antibodies directed against the drug. In these patients, the exacerbation rate was similar to that in placebo-treated patients. In patients on IFN-β1a, neutralizing antibodies can occur first at 3 to 6 months and as late as 18 months. This product tends to be the most antigenic. With IFN-β1a, neutralizing antibodies were found in 22% of early trials of Avonex, but later studies reported that only 2% to 5% of treated patients developed antibodies; this decrease was caused by a formulation change of the drug making it the least antigenic. Percentages for Rebif are intermediate, therefore moderately antigenic, at approximately 12% and can occur in the first 9 to 15 months of treatment, which is the same time frame for antibody production with Avonex. The long-term clinical significance of these findings, however, is still not completely clear, although three recent studies have further confirmed the effect of neutralizing antibodies on relapses, MRI lesions, and progression of disability. Whether these antibodies are truly cross-reactive between products is unknown, as is the duration during which antibodies can be detected. There are no general consensus guidelines regarding when to test for neutralizing antibodies, which assay to use, or what titer cutoff to apply to patients in clinical settings. An important question is whether production of antibodies might be diminished with treatments such as corticosteroids. Another concern of practitioners is the relationship between active ingredients and varying excipients of interferon therapies and the production of neutralizing antibodies. Neutralizing antibodies are seen in approximately 6% of patients treated with natalizumab, and the antibodies seem to diminish efficacy.

We now have experience for more than a decade with MS patients taking DMTs, yet continuing to have more relapses, more lesions on MRI, more disability, and ongoing slippage into SPMS. There is no accepted definition of treatment inadequacy, although the Canadian Multiple Sclerosis Research Council has suggested a relatively simple approach that incorporates the elements of relapse rate, new MRI lesions, and change on the EDSS. If a patient develops significant and persistent interferon antibodies, movement to a noninterferon (glatiramer acetate, natalizumab, fingolimod, mitoxantrone, or possibly rituximab) is reasonable. When failing low-dose interferon, options include changing to a higher dose, more frequent administration of interferon, or changing to a noninterferon. A second option is addition of an immunosuppressant agent, such as monthly methotrexate, cyclosporine, or mycophenolate. As noted above, the addition of natalizumab to IFN-β1b was effective, but produced rare cases of PML, and thus, this combination should not be used. The addition of a statin agent may worsen MS although these results are not definitive.

### SYMPTOMATIC MANAGEMENT

Many of the symptoms of MS do not require pharmacologic management or do not respond to it. This section addresses the primary symptoms in which pharmacologic management may be of benefit. See the preceding section on the treatment of acute exacerbations for a discussion of optic neuritis.

#### Gait Difficulties and Spasticity

Problems with gait can be caused by spasticity, weakness, ataxia, defective proprioception, or a combination of these factors. Spasticity...
is amenable to pharmacologic intervention, whereas physical therapy may be required in treating gait disturbances owing to any of the other factors. Spasticity is encountered commonly and tends to affect the legs more markedly than the arms. Spasticity can result in falls; however, in the later stages of the disease, the increased muscle tone of a spastic limb often lends strength to patients with underlying weakness. Therefore, when using muscle relaxants, one must be careful not to decrease the tone to an extent that ambulation is actually hindered. Baclofen (Lioresal), a γ-aminobutyric acid (GABA) analog, is the preferred agent and usually is started in dosages of 10 mg 3 times daily and titrated upward to achieve the desired response. Most patients achieve a satisfactory response with dosages between 40 and 80 mg/day; however, dosages higher than the recommended daily maximum of 80 mg are required by some patients. A wearing-off is common, however, due to the relatively short duration of action. A longer-acting version of Lioresal is under study. Continuous intrathecal administration of baclofen may be an option for patients unable to tolerate or unresponsive to oral therapy. Baclofen should not be discontinued abruptly to avoid the possibility of seizures. Small doses of diazepam (Valium) (e.g., 0.5–1 mg) often are added to baclofen in patients in whom optimal response has not been achieved.

Another effective agent with a different mechanism of action is tizanidine (Zanaflex). This short-acting, α1-adrenergic agonist acts in the CNS to reduce spasticity by increasing presynaptic inhibition of motor neurons. It appears to have efficacy comparable with that of baclofen. Dosage must be titrated slowly over 2 to 4 weeks, starting with 4 mg at bedtime, with adjustments based on clinical response. Effective tolerated dosages have ranged from 2 to 36 mg/day. Sedation, dizziness, and dry mouth are the most commonly reported adverse effects, but hypotension also can occur, as well as a rare but severe hepatotoxicity. Tizanidine can be added in small dosages to baclofen, sometimes resulting in better results and smaller doses of each drug.

In patients who are unable to tolerate baclofen or tizanidine, diazepam (Valium; 2–10 mg/day), clonazepam (Klonopin; 1–3 mg/day), or dantrolene sodium (Dantrol; 100–400 mg/day), may be considered as alternatives, but they generally are less effective than either baclofen or tizanidine. Mild spasticity also may respond to moderately high doses of gabapentin (Neurontin; 1,800–3,600 mg/day). Tiagabine (Gabitril 8–56 mg/day) may be useful in some patients with spasticity, but side effects can prohibit its use. Pregabalin (Lyrica; 75–300 mg/day) has similar features and mechanism of actions as gabapentin, although pregabalin is approximately 3 times more potent and does not saturate the L-system transporter system in the gastrointestinal system, so it may prove useful in the treatment of spasticity in MS patients.

Botulinum toxin type A (Botox; dose depending on the muscles injected) has been shown to be effective in improving spasticity. The amount of toxin required to exert an effect on spasticity is often too excessive to use safely in the larger muscles; therefore, its use is best limited to smaller areas of focal muscle spasm.

An alternative approach to gait disruption employs K+ channel blockers such as 4-aminopyridine (4-AP). Recent studies have shown that 4-AP may modestly improve walking speed. In early 2010, the FDA approved the use of a long-acting proprietary version of 4-AP, dalfampridine (AmLyra; 20 mg/day), for use in the United States.

DDAVP, desmopresin acetate; TCA, tricyclic antidepressant.
Data from Schapiro, Freedman et al, Mitchell, Goodman et al, Kinn and Larson.

is a problem of constipation, which is worsened by the patient’s natural instinct to limit fluid intake (owing to the increasing urge to urinate). Newer medications include antimuscarinic agents such as trosopium chloride (Sanctura; 40 mg/day), solifenacin succinate (Vesicare; 5–10 mg/day), darifenacin hydrobromide (Enable; 7.5–15 mg/day), and fesoterodine (Toviaz; 4–8 mg/day). As an alternative, the synthetic antidiuretic hormone preparation desmopressin acetate (DDAVP; 0.2–0.6 mg/day) has been reported to be effective in the treatment of urgency and incontinence. Use of DDAVP probably is best limited to bedtime so as to improve sleep and because there can be significant problems with hyponatremia and possible seizures if overused. Patients with significant sphincter dyssynergia may benefit from the oral use of α-adrenergic blockers such as prazosin (Minipress; 10–40 mg/day) or intramuscular use of botulinum toxin type A (Botox; dose depends on the muscles injected).

Intermittent self-catheterization with or without a concomitant anticholinergic agent is recommended in patients with large postvoid urine residual volumes (greater than 100 mL) or when the urinary problem is hyporeflexic in nature (failure to empty). Patients with large postvoid residual volumes are at risk for developing urinary tract infections (UTIs) and often are prescribed urinary acidifiers such as vitamin C or antiseptics such as methenamine mandelate to prevent infections. Antibiotics used for UTI prophylaxis include sulfamethoxazole/trimethoprim, cephalaxin, cinoxacin, and nitrofurantoin.

Constipation is the most common bowel complaint. Many medications (narcotics, anticholinergics) in common use may worsen this problem, as may voluntary water restriction in those patients with urinary urgency and incontinence. Increases in dietary fiber...
and hydration may alleviate this problem, but in some instances laxatives or enemas may be necessary.

**Major Depression**

Major depression is common in patients with MS, and the risk of suicide may be increased markedly compared with healthy subjects.\(^{101}\) Patients should be monitored closely for the development of major depressive symptomatology and treated accordingly (see Chapter 77). Interferon products and natalizumab should be used cautiously in patients with significant depression.

**Sensory Symptoms**

Numbness and paresthesia are frequent sensory complaints but usually do not require treatment. Some MS patients may develop acute or chronic pain syndromes\(^{98}\) such as trigeminal neuralgia and painful dysesthesias, for which treatment is necessary. Carbamazepine (Tegretol; 400–1,200 mg/day) is the preferred agent for the treatment of trigeminal neuralgia. Other agents also commonly used for neuropathic pain include amitriptyline and related tricyclic antidepressants, gabapentin, pregabalin, and duloxetine.

**Sexual Dysfunction**

Sexual dysfunction in both men and women are common in MS, and counseling should be offered to both partners. Sildenafil citrate (Viagra), tadalafl (Cialis), and vardenafl (Levitra) are very effective for men with MS who have erectile dysfunction. Other options for men include alprostadil injection (Caverject) or intraurethral suppositories (MUSE). Viagra is currently being studied in females with MS and sexual dysfunction. In patients needing antidepressant therapy for whom sexual dysfunction is a concern, bupropion is preferable to selective serotonin reuptake inhibitors as it has a much lower incidence of sexual side effects.

**Fatigue**

Fatigue, one of the most common complaints in MS patients, can be severely disabling, but treatment is often overlooked. Typically present in the mid to late afternoon, it can increase with heat exposure, exertion, intercurrent infection, spasticity, weakness, and depression. Amitriptyline hydrochloride (100 mg twice daily) is used often and may offer significant relief.\(^{101,102}\) Methylenephenedate (Ritalin) and related products, and dextroamphetamines (Dexedrine) are used commonly for fatigue in MS. Modafinil (Provigil), at 100 mg twice daily, is also helpful for MS-related fatigue. In patients suffering from both depression and fatigue, a more activating antidepressant such as fluoxetine may be employed.

**Cognition**

Cognitive dysfunction is common in MS, affecting up to 50% or more of patients. It generally manifests itself as word finding difficulties and problems with concentration and short term memory. Cognitive dysfunction can be treated with stimulants or cholinesterase inhibitors.

### COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR MS

A large percentage of patients with MS use complementary and alternative medicine (CAM) instead of, or in addition to, disease-modifying and symptomatic therapies. Common CAM therapies include diet and dietary supplements, such as vitamins, minerals, and herbs. Antioxidant supplements vitamin A, C, E, α-lipoic acid, coenzyme Q10, grape seed, pine bark extracts, mangosteen and acai have suggestive evidence of benefiting MS patients. However, for patients with MS, there is a theoretical risk involved with taking antioxidant supplements owing to their ability to stimulate the immune system (T cells and macrophages). Stimulating the immune system in patients with MS could be counterproductive, possibly worsening or exacerbating their disease, and may counteract the effects of immunomodulators. Other immune-stimulating supplements that should be used with caution are garlic, ginseng (Asian and Siberian), echinacea, cat’s claw, astragalus, alfalfa, and stinging nettle. A few agents that may pose a problem in MS, but may have benefit when taken in moderation, are zinc, melatonin (for insomnia), and dehydroepiandrosterone.\(^{102}\)

In general, there are insufficient data supporting the effectiveness and safety of CAM therapies for MS. However, for patients with MS who are willing to try new approaches with limited evidence, CAM may be a consideration in some cases. Healthcare providers can be a source of objective information regarding the use of CAM for MS and can assist their patients in making the best decision.\(^{102}\)

### INFLUENZA VACCINE RECOMMENDATIONS

A yearly flu shot is recommended for all patients with MS, including patients on any of the DMTs. The intranasal influenza vaccine, Flumist, which is a live, attenuated vaccine, is not recommended for patients with MS, however. As DMTs suppress the immune system, a patient taking one of these medications is at increased risk for developing an infection of the strain of virus given in the vaccine. Live virus vaccines are also more likely to cause an increase in MS disease activity than inactivated virus vaccines. Finally, it is unknown whether there are any direct interactions between DMTs and the intranasal influenza vaccine.\(^{103}\) This information can likely be extrapolated to other vaccines, so if a patient is in need of a vaccination of any kind, “killed” virus vaccines are recommended.

Patients opting to take fingolimod who are varicella zoster virus antibody negative should consider receiving the varicella zoster virus immunization (even though it is a live attenuated vaccine) at least one month prior to beginning fingolimod. This should allow time to mount an antibody response prior to immunosuppression with fingolimod.

### PHARMACOECONOMIC CONSIDERATIONS

As with many therapeutic decisions, economic cost, both to the individual and to society, must be considered. Currently, the annual cost of the DMTs is considerable. The Red Book average wholesale price (used for all products in this chapter) of each of the currently available interferons is between $18,300 and $21,200 per patient per year. Given this expense, it must be remembered that these therapies are not curative and that individual patients may experience variable results. Future investigations evaluating these therapeutic modalities clearly will need to address not only clinical but also economic and humanistic outcomes.

A recent cost-benefit analysis has identified that even more expensive therapies, such as natalizumab, may be cost-effective due to their ability to more effectively reduce the likelihood of relapses, thus resulting in lower treatment costs and hospitalization for acute relapses.\(^{104}\)

### EVALUATION OF THERAPEUTIC OUTCOMES

Response to treatment of acute exacerbations of MS is commonly seen within days. With respect to DMTs, it is important for the clinician to recognize that over the short term (days to weeks), little or no apparent benefit may be noted by either patient or...
Multiple sclerosis is an inflammatory disease of the CNS that strikes young, genetically susceptible individuals living in high-risk geographic areas. Although the exact etiology of MS is unknown, it is likely that MS is an autoimmune disease triggered by an as yet undetermined environmental agent or agents. There is no cure, but quality of life can be improved through symptomatic management. Specific laboratory monitoring for individuals on interferon therapy should include a complete blood count, platelet count, and liver function tests. These should be completed at baseline, every 3 months for 1 year, and every 6 months thereafter. Glatiramer acetate requires no laboratory monitoring. In addition to counseling patients regarding the adverse effects associated with these drugs, pharmacists should actively encourage patients to comply with their prescribed regimens.

**CONCLUSIONS**

Safety monitoring of patients on interferon includes regular laboratory monitoring, patient observation, and questioning for adverse effects or changing disability, and regular neurologic examinations. Specific laboratory monitoring for individuals on interferon therapy should include a complete blood count, platelet count, and liver function tests. These should be completed at baseline, every 3 months for 1 year, and every 6 months thereafter. Glatiramer acetate requires no laboratory monitoring. In addition to counseling patients regarding the adverse effects associated with these drugs, pharmacists should actively encourage patients to comply with their prescribed regimens.

Epilepsy is a disorder that is best viewed as a symptom of disturbed electrical activity in the brain, which may have many etiologies. It is a collection of many different types of seizures that vary widely in severity, appearance, cause, consequence, and management. Seizures that are prolonged or repetitive can be life-threatening. Epilepsy is defined by the occurrence of at least two unprovoked seizures separated by 24 hours. The effect epilepsy has on patients’ lives can be significant and extremely frustrating. It is also important to recognize that seizures can be just one (albeit the most obvious) symptom of an epileptic disorder. Not uncommonly, patients have other comorbid disorders, including depression, anxiety, and potentially neuroendocrine disturbances. Patients with epilepsy also may display neurodevelopmental delay, memory problems, and/or cognitive impairment. Although, by convention, the focus of drug treatment is on the abolition of seizures, clinicians must also try to address these common comorbidities.

**KEY CONCEPTS**

1. Patient-specific treatment goals should be identified as early as possible.
2. Accurate diagnosis and classification of seizure/syndrome type is critical to selection of appropriate pharmacotherapy.
3. Patient characteristics such as age, comorbid conditions, ability to comply with the prescribed regimen, and presence or absence of insurance coverage can also influence the choice of antiepileptic drugs.
4. Pharmacotherapy of epilepsy is highly individualized and requires titration of the dose to optimize antiepileptic drug therapy (maximal seizure control with minimal or no side effects). Approximately 50% to 70% of patients can be maintained on one antiepileptic drug.
5. If the therapeutic goal is not achieved with monotherapy, a second drug can be added or a switch to an alternative single antiepileptic drug can be made. If a second antiepileptic drug is added it should have a different mechanism of action from the first, although there is no clear evidence in humans to support this.
6. Some patients eventually can discontinue antiepileptic drug therapy. Several factors predict successful withdrawal of antiepileptic drugs.
7. The appropriate use of antiepileptic drugs requires a thorough understanding of their clinical pharmacology, including mechanism of action, pharmacokinetics, adverse reactions, and drug interactions, as well as available dosage forms.

**EPIDEMIOLOGY**

Each year, 120 per 100,000 people in the United States come to medical attention because of a newly recognized seizure. At least 8% of the general population will have at least one seizure in a lifetime. However, it is common to have a seizure and not have epilepsy. The rate of recurrence of a first unprovoked seizure within 5 years ranges between 23% and 80%. Children with an idiopathic first seizure and a normal electroencephalogram (EEG) have a particularly favorable prognosis. Some seizures occur as single events resulting from withdrawal of central nervous system (CNS) depressants (e.g., alcohol, barbiturates, and other drugs) or during acute neurologic illnesses or systemic toxic conditions (e.g., uremia or eclampsia). Some patients will have seizures only associated with fever. These febrile seizures do not constitute epilepsy.

The age-adjusted incidence of epilepsy is 44 per 100,000 person-years. Each year, approximately 125,000 new epilepsy cases occur in the United States; only 30% are in people younger than 18 years of age at the time of diagnosis. There is a bimodal distribution in the occurrence of the first seizure, with one peak occurring in newborn and young children and the second peak occurring in patients older than 65 years of age. The relatively high frequency of epilepsy in the elderly is now being recognized.

**ETIOLOGY**

Seizures occur because a group of cortical neurons discharge abnormally in synchrony. Anything that disrupts the normal homeostasis or stability of neurons can trigger hyperexcitability and seizures. Thousands of medical conditions can cause epilepsy, from genetic mutations to traumatic brain injury. A genetic predisposition to seizures has been observed in many forms of primary generalized epilepsy. Patients with mental retardation, cerebral palsy, head injury, or strokes are at an increased risk for seizures and epilepsy. The more profound the degree of mental retardation as measured by the intelligence quotient (IQ), the greater is the incidence of epilepsy. In the elderly, the onset of seizures is typically associated with focal neuronal injury induced by strokes, neurodegenerative disorders (e.g., Alzheimer’s disease), and other conditions. In some cases, if an etiology of seizures can be identified and corrected, the
patient may not require chronic antiepileptic drug (AED) treatment. Patients can also present with unprovoked seizures that do not have an identifiable cause, and thus by definition have idiopathic or cryptogenic epilepsy. Idiopathic etiology is the term used for suspected genetic cause, whereas cryptogenic etiology is used if no obvious cause is found for focal-onset seizures.

Many factors have been shown to precipitate seizures in susceptible individuals. Hyperventilation can precipitate absence seizures. Excessive sleep, sleep deprivation, sensory stimuli, emotional stress, and hormonal changes occurring around the time of menses, puberty, or pregnancy have been associated with the onset of or an increased frequency of seizures. A careful drug history should be obtained from patients presenting with seizures because theophylline, alcohol, high-dose phenothiazines, antidepressants (especially maprotiline or bupropion), and street drug use have been associated with provoking seizures. Perinatal injuries and small gestational weight at birth are also risk factors for the development of partial-onset seizures. Immunizations have not been associated with an increased risk of epilepsy.

**PATHOPHYSIOLOGY**

Seizures result from excessive excitation, or in the case of absence seizures, from disordered inhibition of a large population of cortical neurons. This is reflected on EEG as a sharp wave or spike. Initially, a small number of neurons fire abnormally. Normal membrane conductances and inhibitory synaptic currents break down, and excess excitability spreads, either locally to produce a focal seizure or more widely to produce a generalized seizure. This onset propagates by physiologic pathways to involve adjacent or remote areas. The clinical manifestations depend on the site of the focus, the degree of irritability of the surrounding area of the brain, and the intensity of the impulse.

There are multiple mechanisms that might contribute to synchronous hyperexcitability, including: (1) alterations in the distribution, number, type, and biophysical properties of ion channels in the neuronal membranes; (2) biochemical modifications of receptors; (3) modulation of second messaging systems and gene expression; (4) changes in extracellular ion concentrations; (5) alterations in neurotransmitter uptake and metabolism in glial cells; and (6) modifications in the ratio and function of inhibitory circuits. In addition, local neurotransmitter imbalances could be a potential mechanism for focal epileptogenesis. Transitory imbalances between the main neurotransmitters, glutamate (excitatory) and γ-aminobutyric-acid (GABA) (inhibitory), and neuromodulators (e.g., acetylcholine, norepinephrine, and serotonin) might play a role in precipitating seizures in susceptible patients.

Control of abnormal neuronal activity with AEDs is accomplished by elevating the threshold most likely involves stabilization of neuronal membranes, whereas limiting the propagation involves depression of synaptic transmission and reduction of nerve conduction.

Prolonged seizures and continued exposure to glutamate can result in neuronal injury in vulnerable neuronal populations resulting in functional deficits, primarily in memory, and in permanent changes of wiring of the neuronal circuitry. Sprouting and reorganization of neuronal projections might lead to a chronic susceptibility to seizures, neuronal destruction, and brain damage. However, limited degree of neurogenesis in the hippocampal pathways has been induced by epileptic seizures. The role of these newly born neurons is not well understood.

**CLINICAL PRESENTATION**

The International League Against Epilepsy has proposed two major schemes for the classification of seizures and epilepsies: the International Classification of Epileptic Seizures and the International Classification of the Epilepsies and Epilepsy Syndromes. The International Classification of Epileptic Seizures (Table 65–1) combines the clinical description with certain electrophysiologic findings to classify epileptic seizures. Seizures are divided into two main pathophysiologic groups—partial seizures and generalized seizures—by EEG recordings and clinical symptomatology.

Partial (focal) seizures begin in one hemisphere of the brain and—unless they become secondarily generalized—result in an asymmetric motor manifestation. Partial seizures manifest as alterations in motor functions, sensory or somatosensory symptoms, or automatisms. Partial seizures with no loss of consciousness are classified as simple partial (SP). In some cases, patients will describe somatosensory symptoms as a “warning” prior to the development of a generalized tonic clonic (GTC) seizure. These warnings are, in fact, simple partial seizures and frequently are termed auras.

Partial seizures with an alteration of consciousness are described as complex partial (CP). With CP seizures, the patient can have automatisms, periods of memory loss, or aberrations of behavior. Some patients with CP epilepsy have been mistakenly diagnosed as having psychotic episodes. CP seizures also can progress to GTC seizures. Patients with CP seizures typically are amnestic to these events. A partial seizure that becomes generalized is referred to as a secondarily generalized seizure.

Generalized seizures have clinical manifestations that indicate involvement of both hemispheres. Motor manifestations are bilateral, and there is a loss of consciousness. Generalized seizures can be further subdivided by EEG and clinical manifestations. Generalized absence seizures are manifested by a sudden onset, interruption of ongoing activities, a blank stare, and possibly a brief upward rotation of the eyes. They generally occur in young children through adolescence. It is important to differentiate absence seizures from complex partial seizures.

Data from Commission on the Classification and Terminology of the International League Against Epilepsy.
With GTC seizures there is a sudden sharp tonic contraction of muscles followed by a period of rigidity and clonic movements. During the seizure, the patient may cry or moan, lose sphincter control, bite the tongue, or develop cyanosis. After the seizure, the patient may have altered consciousness, drowsiness, or confusion for a variable period of time (postictal period) and frequently goes into a deep sleep. Tonic and clonic seizures can also occur separately.

Brief shock-like muscular contractions of the face, trunk, and extremities are known as myoclonic jerks. They can be isolated events or rapidly repetitive. A sudden loss of muscle tone is known as an atonic seizure, which may present as a head drop, the dropping of a limb, or a slumping to the ground. These patients often wear protective head ware to prevent trauma.

The International Classification of Epilepsies and Epilepsy Syndromes adds components such as age of onset, intellectual development, findings on neurologic examination, and results of neuroimaging studies to define epilepsy syndromes more fully. Syndromes can include one or many different seizure types (e.g., Lennox-Gastaut syndrome). The syndromic approach includes seizure type(s) and possible etiologic classifications (e.g., idiopathic, symptomatic, or unknown). Idiopathic describes syndromes that are presumably genetic but also those in which no underlying etiology is documented or suspected. A family history of seizures is commonly present, and neurologic function is essentially normal except for the occurrence of seizures. Symptomatic cases involve evidence of brain damage or a known underlying cause. A cryptogenic syndrome is assumed to be symptomatic of an underlying condition that cannot be documented. Unknown or undetermined is used when no cause can be identified. This syndromic classification requires more information and is more important for prognostic determinations and response to treatment than for a classification based simply on seizure type.

### CLINICAL PRESENTATION OF EPILEPSY

#### General
In most cases, the healthcare provider will not be in a position to witness a seizure. Many patients (particularly those with CP or GTC seizures) are amnestic to the actual seizure event. Obtaining an adequate history and description of the ictal event (including time course) from a witness is critically important. With treatment the typical clinical presentation of the seizure may change.

#### Symptoms
Symptoms of a specific seizure will depend on seizure type. Although seizures can vary between patients, they tend to be stereotyped within an individual.
- **CP seizures** can include somatosensory or focal motor features.
- **CP seizures** are associated with altered consciousness.
- Absence seizures can be almost nondetectable with only very brief (seconds) periods of altered consciousness.
- GTC seizures are major convulsive episodes and are always associated with a loss of consciousness.

#### Signs
Interictally (between seizure episodes), there are typically no objective or pathognomonic signs.

#### Laboratory Tests
There are currently no diagnostic laboratory tests for epilepsy. In some cases, particularly following GTC (or perhaps CP) seizures, serum prolactin levels can be transiently elevated.

### Laboratory Tests
- Laboratory tests can be done to rule out treatable causes of seizures (e.g., hypoglycemia, altered electrolyte concentrations, infections, etc.) that do not represent epilepsy.

#### Other Diagnostic Tests
- **EEG** is very useful in the diagnosis of various seizure disorders.
- An epileptiform EEG is found in only approximately 50% of the patients who have epilepsy.
- A prolactin serum level obtained within 10 to 20 minutes of a tonic-clonic seizure can be useful in differentiating seizure activity from pseudoseizure activity but not from syncope.
- Although magnetic resonance imaging (MRI) is very useful (especially imaging of the temporal lobes), a computed tomography (CT) scan typically is not helpful except in the initial evaluation for a brain tumor or cerebral bleeding.

### TREATMENT

#### DESIRED OUTCOME
1. The ideal goal of treatment for epilepsy is complete elimination of seizures and no side effects with an optimal quality of life (QOL). The best QOL is associated with a seizure-free state.
2. A balance must be achieved between efficacy and side effects without compromising seizure control. As patients become seizure free, because therapy is continued for many years (often a lifetime), chronic side effects must be considered. If the patient is overly sedated or develops other significant side effects, some seizure control may have to be sacrificed to improve functioning. The patient should be involved in deciding what balance between frequency of seizures and occurrence of side effects is most appropriate. The newer AEDs offer alternatives for balancing seizure frequency and drug side effects.
3. Providing optimal QOL also requires assessing all the concerns of patients with epilepsy, such as, issues about driving, economic security, forming relationships, safety, social isolation, social stigma, and so on. Patients with epilepsy can also have other neuropsychiatric comorbidities such as depression, anxiety, and sleep disturbances that need treatment. Depression has been shown to have a significant impact on QOL in the patient with treatment-resistant epilepsy.

#### GENERAL APPROACH TO TREATMENT
1. The general approach to treatment involves assessment of seizure type and frequency, identification of treatment goals, development of a care plan, and a plan for follow-up evaluation. During the assessment phase, it is critical to establish an accurate diagnosis of the seizure type and classification in order to select the appropriate initial AEDs. Patient-specific treatment goals must be identified, and these can change over time. Despite appropriate AED treatment, approximately 30% to 35% of patients are refractory to treatment. In this setting, seizure freedom may not be obtained, and more obtainable goals should be established (e.g., decrease in the number of seizures and minimized drug adverse effects).
2. Patient characteristics such as age, medical condition, ability to comply with a prescribed regimen, and insurance coverage also should be explored because these can influence AED choices or help to explain nonadherence to the regimen, a lack of response, or unexpected adverse effects.
Once the assessment is complete, for patients with new-onset seizures, the choice is whether to use drug therapy and, if so, which one. For a patient with long-standing epilepsy, adequacy of the current medication regimen must be evaluated. An AED should not be considered ineffective unless the patient has experienced unacceptable adverse effects with continued seizures.

If a decision is made to start AED therapy, monotherapy is preferred, and approximately 50% to 70% of all patients with epilepsy can be maintained on one drug. However, many of these patients are not seizure free. The percentage of patients who are seizure free on one drug varies by seizure type. After 12 months of treatment, the percentage who are seizure free is highest for those who have only GTC seizures (48%–55%), lowest for those who have only CP seizures (23%–26%), and intermediate for those with mixed seizure types (25%–32%). Combining AEDs with different mechanisms of action to achieve freedom from seizures may be advantageous, although this approach is as yet unproven. Approximately 65% of patients can be expected to be maintained on one AED and be considered well controlled, although not necessarily seizure free.

Of the 35% of patients with unsatisfactory control, 10% will be well controlled with a two-drug treatment. Of the remaining 25%, 20% will continue to have unsatisfactory control despite multiple drug treatment. There may be a genetic predisposition to epilepsy that is refractory to drug therapy. Some of these patients may become candidates for surgery or vagal nerve stimulator.

Once the care plan is established, an AED is selected. Patient education and assurance of patient understanding of the plan are essential. Detailed directions regarding titration, what to do in the event of a treatment-emergent side effect, and what to do if a seizure occurs must be provided to patients. Documentation of the assessment, care plan, and educational process is essential. Providing the patient with a seizure and side-effect diary will assist in the follow-up and evaluation phase. At the follow-up stage of treatment (which can be done in the hospital, clinic, pharmacy, or by phone), the treatment goals must be reviewed. If the goal has been achieved, new goals should be identified. For example, if the GTC seizures are now controlled, the goal may be to control partial seizures. If a patient fails to respond to the first AEDs, trials with other AEDs should be attempted as appropriate. Completion of the evaluation often requires a reassessment of the patient and development of a new care plan taking into account patient compliance, efficacy, and safety of the initial treatment.

Medication noncompliance can be the single most common reason for treatment failure. It is estimated that up to 60% of patients with epilepsy are noncompliant. The rate of noncompliance is increased by the complexity of the drug regimen and by doses taken 3 and 4 times a day. Frequent uncontrolled seizures can also predispose a patient to noncompliance secondary to confusion over whether the drug was taken. Noncompliance is not influenced by age, sex, psychomotor development, or seizure type.

Difference of opinion exists on the most appropriate time to initiate AED therapy. Treatment decisions vary depending on individual patient clinical characteristics and circumstances. Some clinicians start AED treatment after the first seizure, whereas others do not initiate treatment until a second, unprovoked seizure has occurred. Still others initiate prophylactic treatment following a CNS insult thought likely to cause epilepsy eventually (e.g., stroke or head trauma). Drug treatment may not be indicated when seizures have minimal impact on patients’ lives or when there has been only a single seizure. If a patient presents after a single isolated seizure, one of three treatment decisions can be made: treat, possibly treat, or do not treat. These decisions are based on the probability of the patient having a second seizure. For patients with no risk factors, the probability of a second seizure is less than 10% in the first year and approximately 24% by the end of 2 years. If risk factors are present, the recurrence rate can be as high as 80% after 5 years. The decision on whether to start AED therapy often depends on patient-specific factors such as epilepsy syndrome, seizure etiology, presence of a neuroanatomic defect, and the EEG, as well as, the patient’s lifestyle and preferences. Patients who have had two or more seizures generally should be started on AEDs.

### WHEN TO STOP ANTI-EPILEPTIC DRUGS

The AEDs used to control seizures may not need to be given for a lifetime. Polypharmacy can be reduced, and some patients can discontinue AEDs altogether. The drug considered less appropriate for the seizure type (or the agent deemed most responsible for adverse effects) should be discontinued first. In some cases, decreasing the number of AEDs can decrease side effects and increase cognitive abilities. This improvement in cognition may be small, especially if the patient is on a drug that primarily affects psychomotor speed with less effect on higher-order cognitive functioning.

Factors favoring successful withdrawal of AEDs include a seizure-free period of 2 to 4 years, complete seizure control within 1 year of onset, an onset of seizures after age 2 but before age 35, and a normal neurologic examination and EEG. Factors associated with a poor prognosis in discontinuing AEDs, despite a seizure-free interval, include a history of a high frequency of seizures, repeated episodes of status epilepticus, a combination of seizure types, and development of abnormal mental functioning. A 2-year seizure-free period is suggested for absence and rolandic epilepsy, whereas a 4-year seizure-free period is suggested for SP, CP, and absence seizures associated with tonic-clonic seizures. AED withdrawal generally is not suggested for patients with juvenile myoclonic epilepsy, absence with clonic-tonic-clonic seizures, or clonic-tonic-clonic seizures. The American Academy of Neurology (AAN) has issued guidelines for discontinuing AEDs in seizure-free patients. After assessing the risks and benefits to both the patient and society, AED withdrawal can be considered in a patient meeting the following profile: seizure free for 2 to 5 years, a history of a single type of partial seizure or primary GTC seizures, a normal neurologic exam and normal IQ, and an EEG that has normalized with treatment. When these factors are present, the relapse rate is expected to be less than 32% for children and 39% for adults.
AED withdrawal should be done gradually, especially in patients with profound developmental disabilities. Some patients will have a recurrence of seizures as the AEDs are withdrawn. Sudden withdrawal is associated with the precipitation of status epilepticus. Withdrawal seizures are of particular concern for agents such as benzodiazepines and barbiturates. Seizure relapse has been reported to be more common if these AEDs are withdrawn over 1 to 3 months compared to over 6 months.

The risk of seizure relapse has been estimated at 10% to 70%. A meta-analysis determined that the relapse rate was 25% after 1 year and 29% after 2 years. Recurrence of seizures tends to occur early with at least one-half of the recurrences within 6 months of AED withdrawal and 60% to 90% within 1 year. Patients who relapse will generally become seizure free and in remission after AEDs are restarted although not necessarily immediately. The underlying epilepsy syndrome appears to determine prognosis for long-term remission.15

**CLINICAL CONTROVERSY**

It is not entirely clear which patients with epilepsy will require lifelong treatment. Although many clinicians feel that AED therapy is lifelong, others would argue that certain patients with idiopathic epilepsy and a normal neurologic examination and EEG are candidates for AED withdrawal following a prolonged period of seizure freedom (e.g., greater than 2–3 years). A large amount of the data supporting discontinuing AEDs has been obtained from children. Some adults will be reticent to discontinue AED therapy even if the clinician is in favor of it because of the fear of having a seizure and the consequences (e.g., loss of driver’s license) that it would entail. The patient should agree and must be a willing participant in the plan to reduce or withdraw AED therapy.

**NONPHARMACOLOGIC THERAPY**

Nonpharmacologic therapy for epilepsy includes diet, surgery, and vagus nerve stimulation (VNS). A vagal nerve stimulator is an implanted medical device that is FDA approved for use as adjunctive therapy in reducing the frequency of seizures in adults and adolescents older than 12 years of age with partial-onset seizures that are refractory to AEDs. It is also used off-label in the treatment of refractory primary generalized epilepsy. The mechanisms of anti-seizure actions of VNS are unknown. Human clinical studies have shown that VNS changes the cerebrospinal fluid (CSF) concentration of inhibitory and stimulatory neurotransmitters and activates specific areas of the brain that generate or regulate cortical seizure activity through increased blood flow. There is experimental evidence to suggest that the anticonvulsant effect of VNS is mediated by the locus coeruleus.16

The VNS device is relatively safe. It may also have a positive effect on mood and behavior, often independent of seizure reduction. The most common side effect associated with stimulation is hoarseness, voice alteration, increased cough, pharyngitis, dyspnea, dyspepsia, and nausea. Serious adverse effects reported include infection, nerve paralysis, hypoesthesia, facial paresis, left vocal cord paralysis, left facial paralysis, left recurrent laryngeal nerve injury, urinary retention, and low-grade fever. In the VNS studies, the percentage of patients who achieved a 50% or greater reduction in their seizure frequency (responders) ranged from 23% to 50%.

Surgery is the treatment of choice in selected patients with refractory focal epilepsy.17 The success rate is between 80% and 90% in properly selected patients. Surgery reduces the risk of epilepsy-associated death, and it may also improve depression and anxiety in refractory epilepsy patients.18,19 A recent systematic review/meta-analysis of published evidence of temporal lobe patients with pharmacoresistant epilepsy concluded that the combination of surgery with medical treatment is four-times as likely as medical treatment alone to achieve freedom from seizures.20 A National Institutes of Health Consensus Conference identified three absolute requirements for surgery. They are (1) an absolute diagnosis of epilepsy, (2) failure on an adequate trial of drug therapy, and (3) definition of the electroclinical syndrome. A focus in the temporal lobe has the best chance for a positive outcome; however, extratemporal foci can be excised successfully in more than 75% of patients. The procedure is not without risk. Learning and memory can be impaired postoperatively, and general intellectual abilities are also affected in a small number of patients. Surgery may be particularly useful in children with intractable epilepsy. Patients may need to continue AED therapy for a period of time following successful epilepsy surgery, but dosage reduction may be achievable.17,21

The ketogenic diet, devised in the 1920s, is high in fat and low in carbohydrates and protein, and it leads to acidosis and ketosis. Protein and calorie intake are set at levels that will meet requirements for growth. Most of the calories are provided in the form of heavy cream and butter. No sugar is allowed. Vitamins and minerals are supplemented. Medium-chain triglycerides can be substituted for the dietary fats. Fluids are also controlled. It requires strict control and parent compliance. Although some centers find the diet useful for refractory patients, others have found that it is poorly tolerated by patients. Long-term effects include kidney stones, increased bone fractures, and adverse effects on growth.22 An international consensus statement has been published which offers recommendations for the clinical management of the patient with epilepsy using various forms of the ketogenic diet which may help with tolerability, including the use of the modified Atkins diet and the Low Glycemic Index Treatment.23

**PHARMACOLOGIC THERAPY**

Optimal management of epilepsy requires that AED treatment be individualized. Different patient groups (e.g., children, women of child-bearing potential, and the elderly) may be better suited to receive one AED than another by virtue not only of seizure type but also of susceptibility or relative risk for certain adverse effects. These issues are highlighted further below.

- Selection and optimization of AED therapy require not only an understanding of drug mechanism(s) of action and spectrum of clinical activity but also an appreciation of pharmacokinetic variability and patterns of drug-related adverse effects. An AED must be effective for the specific seizure type being treated. The drug treatments of first choice depend on the type of epilepsy, and drug-specific adverse effects and patient preferences. Ultimately, AED effectiveness is the result of the interaction of each of these factors. A suggested algorithm for a general approach to the treatment of epilepsy is shown in Figure 65–1.

**Table 65–3** provides evidenced-based treatment recommendations by three professional/regulatory bodies.24–28 In addition, recommendations from a U.S. panel of experts, which included more recent drug treatment data compared to the AAN-American Epilepsy Society (AES) recommendations are included.29

The mechanism of action of most AEDs can be categorized as (1) affecting ion channel kinetics, (2) augmenting inhibitory neurotransmission, or (3) modulating excitatory neurotransmission. Augmentation in inhibitory neurotransmission includes increasing CNS concentrations of GABA, whereas efforts to decrease excitatory neurotransmission are primarily focused on decreasing

(or antagonizing) glutamate and aspartate neurotransmission. AEDs that are effective against GTC and partial seizures probably reduce sustained repetitive firing of action potentials by delaying recovery of sodium channels from activation. Drugs that reduce corticothalamic T-type calcium currents are effective against generalized absence seizures. Myoclonic seizures respond to drugs that enhance GABA<sub>A</sub>-receptor inhibition. In addition to mechanism of action, awareness of pharmacokinetic properties (Table 65–4), adverse effects (Table 65–5), AED-AED interactions (Table 65–6), and AED metabolic pathway as well as inhibitor or inhibitory effects on liver (Table 65–7) can aid in the optimization of AED therapy. Pharmacokinetic interactions are a common complicating factor in AED selection. Interactions can occur in any of the pharmacokinetic processes: absorption, distribution, metabolism or elimination. Caution should be used when AEDs are added to or withdrawn from a drug regimen.

Adverse effects of AEDs can be divided into acute and chronic (see Table 65–5). Acute effects can be dose/serum concentration—related or idiosyncratic. Concentration-dependent effects are common and troublesome but not usually life-threatening. Neurotoxic adverse effects are encountered commonly and can include sedation, dizziness, blurred or double vision, difficulty with concentration, and ataxia. In many cases these effects can be alleviated by decreasing the dose or avoided in some cases by titrating the dose upward very slowly. Most idiosyncratic reactions are mild, but they can be more serious if the hypersensitivity involves one or more organ systems. Other idiosyncratic side effects including hepatitis or blood dyscrasias are serious but rare.

Acute organ failure, when it occurs, generally occurs within the first 6 months of AED therapy. Unfortunately, laboratory screening evaluations of blood and urine typically are not helpful in predicting or detecting the early stage of severe reactions and generally are not recommended in asymptomatic patients. An exception to this is in the screening of patients of Southeast Asian heritage for HLA-B*1502 antigen who are to receive carbamazepine and possibly phenytoin. There is a strong association between the presence of this antigen and Stevens—Johnson syndrome. 36 In any patient, laboratory assessment, including white blood cell counts and liver function tests, may be reasonable if the patient reports an unexplained illness (e.g., lethargy, vomiting, fever, or rash). 37 It is important to note that patients dosed and maintained within “therapeutic ranges” are also capable of experiencing toxicities to AEDs. 32 Another potential long-term adverse effect of AED treatment is osteomalacia and osteoporosis. 36, 39 The bone disorders associated with AED use are a heterogeneous group of disorders, ranging from asymptomatic high-turnover disease, with findings of normal bone mineral density, to markedly decreased bone mineral density sufficient to warrant the diagnosis of osteoporosis. While the etiology of

these osteopathies is uncertain, it has been hypothesized that certain drugs, including phenytoin, phenobarbital, carbamazepine, oxcarbazepine, felbamate, and valproic acid, may interfere with vitamin D metabolism. Whether the other AEDs cause these effects is unknown, however, current evidence suggests that lamotrigine does not. Common laboratory findings in these patients include elevated bone-specific alkaline phosphatase concentration, intact parathyroid hormone, and decreased serum calcium and 25-OH vitamin D concentrations. Patients receiving these drugs should receive supplemental vitamin D and calcium, as well as bone mineral density testing if other risk factors for osteoporosis are present.

The comparative effects of AEDs on cognition have been difficult to evaluate because of differences or inconsistencies in study design, seizure types studied, control for serum drug concentrations, and the neuropsychologic tests used. In general, there are not large differences between the older drugs, although the barbiturates phenobarbital and primidone appear to cause more cognitive impairment than other commonly used AEDs. Phenobarbital, particularly when serum concentrations are above the commonly accepted therapeutic range, may have a greater effect on motor function and speed. Among the older AEDs, valproic acid may cause less impairment of cognition. Improvement in cognition has been reported in patients switched from phenytoin or phenobarbital to valproic acid. However, these improvements are subtle if patients are in the same relative area of the therapeutic range. Patients changed from polytherapy to monotherapy also may demonstrate improvement in cognition. Some of the newer agents are believed to cause fewer neurobehavioral or cognitive effects. Among the newer AEDs, gabapentin and lamotrigine have been shown in several studies to cause fewer cognitive impairments compared with older agents, such as carbamazepine. Conversely, topiramate may cause substantial cognitive impairment, particularly when used at high doses or during rapid dose escalation. In addition, these patients may not be fully aware of their deficits. AED treatment itself may sometimes worsen seizures due to improper AED selection for a specific seizure type or syndrome or can represent a paradoxical toxic effect of the drug.

Because most adult patients have localization-related (partial-onset) seizures, the most widely used AEDs traditionally have been carbamazepine, phenobarbital, phenytoin, and valproic acid.

TABLE 65-7 Antiepileptic Drugs Elimination Pathways and Major Effects on Hepatic Enzymes

For CP seizures, these AEDs have similar efficacy.46,49 Of these, carbamazepine and phenytoin are the most commonly prescribed AEDs for partial seizures in the United States. This preference is largely based on data derived from two landmark trials conducted through the Veterans Administration (VA) Epilepsy Cooperative Study Group. In the first of these trials, patients with new-onset partial or generalized epilepsy were randomized to receive either carbamazepine, phenobarbital, phenytoin, or primidone.48 After 3 years, patients who received either carbamazepine or phenytoin were equally likely and patients on phenobarbital or primidone were least likely to have remained on their originally assigned treatment. Thus, carbamazepine and phenytoin were considered the drugs of first choice in patients with new-onset partial or generalized seizures. Carbamazepine was associated with fewer side effects. A follow-up study using almost identical methods compared carbamazepine and valproic acid.49 Carbamazepine- and valproic acid–treated groups had equal retention rates for tonic–clonic seizures. Carbamazepine was superior to valproic acid for efficacy in the treatment of partial seizures. Valproic acid caused slightly more adverse effects.

Based primarily on these trials, carbamazepine has been recognized as the AED of first choice for partial seizures. Several of the newer generation AEDs are now proving to be reasonable alternatives. The newer AEDs were first approved as adjunctive therapy for patients with refractory partial seizures. Monotherapy trials with several of these newer agents including lamotrigine, gabapentin, topiramate, oxcarbazepine and levetiracetam have now been completed.50–52 Comparisons between lamotrigine and older agents including carbamazepine and phenytoin as initial monotherapy for partial seizures have been conducted in Europe, and the results suggest comparable effectiveness and perhaps better tolerability for lamotrigine, particularly in elderly patients. In a large, unblinded, randomized, controlled trial in hospital based outpatient clinics in the United Kingdom, lamotrigine was found to be clinically better than carbamazepine for time to treatment failure outcomes in newly diagnosed patients with partial seizures; lamotrigine was determined to be a cost effective alternative to carbamazepine. Other drugs studied in this trial were gabapentin, oxcarbazepine, and topiramate.53 Results from a VA cooperative trial designed to compare gabapentin, lamotrigine, and carbamazepine in newly diagnosed elderly patients with partial seizures found that lamotrigine efficacy is comparable with that of both gabapentin and carbamazepine, and is better tolerated than carbamazepine but equal to gabapentin in this population.54 Clinical data suggest that in newly diagnosed patients, oxcarbazepine is as effective as phenytoin, valproic acid, and immediate-release carbamazepine, with perhaps fewer adverse effects. Close examination of the conversion to monotherapy trials suggests that oxcarbazepine demonstrates efficacy even in patients who previously had an inadequate response to carbamazepine, in spite of their structural similarity. Lastly, levetiracetam in a one-year study was found to have equal efficacy and tolerability when studied against controlled-release carbamazepine.55

In addition, several monotherapy trials using an active control or placebo design have also been conducted. Although these study designs provide evidence of efficacy for the newer drugs, because the comparison is between active drug and placebo in patients who continue to have seizures in spite of current treatment with standard AEDs, it is difficult to compare the efficacy of the newer drugs directly with the older AEDs. Generally speaking, the newer AEDs appear to have comparable efficacy to the older agents and are perhaps better tolerated.

To date, among the newer generation agents, lamotrigine, oxcarbazepine, and topiramate have received FDA approval for use as monotherapy in patients with partial seizures. Phenobarbital and primidone are also useful in partial seizures, but sedation and cognitive adverse effects limit their utility. Felbamate, which has monotherapy approval, is effective but has been associated with some significant side effects. Interpretation of monotherapy trials with the newer AEDs can be daunting owing to the unique study designs and specific patient populations employed. Withholding an effective AED (i.e., giving placebo) in patients with epilepsy is generally considered unethical. For more information the reader is referred to published reviews.56

Primarily generalized seizures such as absence seizures may respond differently pharmacologically than other seizure types. Phenytoin, phenobarbital, and carbamazepine, although effective in GTC and partial seizures, are ineffective for absence seizures, and in some cases, can precipitate an increase in seizure frequency. Absence seizures are best treated with ethosuximide, valproic acid, and perhaps lamotrigine. For levetiracetam, topiramate, and zonisamide, additional data are needed to confirm efficacy. Oxcarbazepine, gabapentin, and tiagabine do not appear to be effective in treating absence seizures, and can worsen this condition.

CYP, cytochrome P450 isoenzyme system; GT, glucuronyltransferase.

Data from Faught;1 Leppik;1 Patsalos et al;10 Holford and Lapointe;11 Cado et al;14 and Sabol [package insert].15
in some patients. If the patient has a combination of absence and other generalized or partial seizures, valproic acid or lamotrigine is the preferred first choice because they are effective for absence and other seizure types. If valproic acid is ineffective in treating a mixed seizure disorder that includes absence, ethosuximide could be used in combination with another AED.

The traditional treatment of tonic-clonic seizures is phenytoin; however, carbamazepine and valproic acid are increasingly used because these AEDs have a lower incidence of side effects with equal efficacy. Valproic acid generally is considered the drug of first choice for atonic seizures and for juvenile myoclonic epilepsy (JME). Lamotrigine and perhaps topiramate and zonisamide can be alternative agents for these seizure types. Levetiracetam has received FDA approval as an adjunctive treatment of myoclonic seizures in patients with JME.

Results of a large, unblinded, randomized, controlled trial conducted in patients with new-onset generalized and unclassified epilepsy outpatients in the United Kingdom has helped to define the role of the newer generation drugs. These researchers found that for idiopathic generalized epilepsy, valproic acid was significantly better tolerated than topiramate and more efficacious than lamotrigine. Serum concentrations of the older AEDs should be viewed as a tool with which to optimize therapy for an individual patient, not as a therapeutic end point in itself. The serum concentration is a target that should be correlated with clinical response. The desired outcome is the cessation of seizures without side effects. Seizure control can occur before the “minimum” of the published therapeutic range is achieved, and side effects can appear before the “maximum” of the range is achieved. Some patients may need and tolerate concentrations beyond the maximum. The therapeutic range for AEDs can be different for different seizure types. Serum concentrations may need to be higher to control CP seizures than to control tonic-clonic seizures. Clinicians should define a therapeutic range for an individual patient above which there are side effects and below which the patient experiences seizures. Then serum levels can be useful to document lack of efficacy, loss of efficacy, noncompliance, and to determine how much room there is to increase a dose based on expected toxicity. Depending on the AED, serum levels can also be useful in patients with significant renal and/or hepatic disease, patients taking multiple drugs, and women who are pregnant or taking oral contraceptives (OCs). Therapeutic concentration ranges have not been clearly defined for some of the second generation AEDs.

**THERAPEUTIC CONSIDERATIONS IN THE ELDERLY AND YOUNG**

Use of AEDs in the elderly and young can pose special challenges. Avoidance of AEDs that interact with other medications that the elderly are often taking is of utmost importance. Many of the AEDs are inducers or inhibitors of the CYP450 system, which can adversely affect the drug level of concomitantly administered drugs. Hypoalbuminemia is common in the elderly, and can make monitoring and adjustment of serum drug levels of highly albumin-bound AEDs, such as phenytoin, valproic acid, and tiagabine, problematic. The elderly also experience body mass changes, such as an increase in fat to lean body mass or decrease in body water, which can affect the volume of distribution of some drugs, and therefore possibly the elimination half-life. In addition, declining renal and/or hepatic function can occur in the elderly, which can require a lower dose of the AED. Lastly, the pharmacodynamic response to AEDs can change with aging such that elderly patients may be more sensitive to various neurocognitive adverse effects. Also, elderly patients’ seizures may be controlled at relatively lower total serum concentrations.

For neonates and infants, an increase in the total body water to fat ratio and a decrease in serum albumin and α-acid glycoprotein can result in volume of distribution changes that can affect the elimination half-life of the AEDs. In addition, newborns up to the age of 2 to 3 years display decreased efficiency in renal elimination, with newborns being the most affected. Hepatic activity is also reduced in this population. However, by age 2 to 3 years, hepatic activity is more robust than that seen in adults. Therefore, children require higher doses of many of the AEDs than adults, whereas neonates and infants require lower doses. Lastly, rapidly changing and sometimes inconsistent metabolism in the patient groups above makes therapeutic drug monitoring especially important even though the definition of therapeutic blood level is less certain in these patients than in adults.

**THERAPEUTIC CONSIDERATIONS IN WOMEN (AND MEN)**

Many hormones influence brain electrical excitability, and estrogen and progesterone may interact in complex ways to alter neuronal excitability and protein synthesis. Estrogen has a slight proconvulsant effect, whereas progesterone exerts a mild anticonvulsant effect. Estrogen has a mild inhibitory effect on GABA receptors, potentiates excitatory glutaminergic activity, and can promote the development of kindling. Progesterone has the opposite effect and appears to potentiate GABA receptor activity and reduce neuronal discharge rates. AEDs, especially hepatic metabolizing enzyme inducers, increase the metabolism of these hormones and induce the production of sex hormone-binding globulin. This may lead to decreases in the unbound fraction of the hormone. Enzyme-inducing AEDs, including topiramate and oxcarbazepine at higher doses, can cause treatment failures in women taking OCs owing to induction of the metabolism of ethinyl estradiol and progestin. This may also be an issue with rufinamide, lamotrigine, and felbamate, all of which have a small effect in decreasing the bioavailability of combination oral contraceptives (OCs). A supplemental form of birth control, in addition to OCs, is advised if breakthrough bleeding occurs. However, medroxyprogesterone depot injection, copper intrauterine devices, and hormone-release intrauterine systems are not affected by AEDs. There are no data available on the efficacy of the emergency contraceptive pill in patients taking these AEDs, but it has been suggested that women use twice the normal dose of the postcoital pill. Valproic acid, benzodiazepines, and most of the newer AEDs, such as gabapentin, levetiracetam, tiagabine, zonisamide, vigabatrin, and lacosamide, are not enzyme inducers and have not been implicated in reducing contraceptive effectiveness. Of note, OCs lower lamotrigine’s serum level significantly and lower valproic acid’s level about 20%.

In some women, vulnerability to seizures is highest just before and during the menstrual flow (catamenial seizures) and at the time of ovulation. The increased susceptibility to seizures during those catamenial periods is associated with a slight increase of estrogen relative to progesterone. The risk of catamenial epilepsy is estimated at 12.5%, but it may be as high as 50% in women with epilepsy. This pattern of seizure exacerbation can also be related to progesterone withdrawal and changes in the estrogen-to-progesterone ratio. Conventional AEDs should be used as primary agents but intermittent supplementation with higher dose of AED or benzodiazepines should be considered. Acetazolamide also has been used during catamenial periods but with variable and limited success. Hormonal therapy with progesterational agents, particularly cyclic natural progesterone therapy, may be effective. Reproductive endocrine disorders are common in women with epilepsy and include menstrual irregularity, infertility, sexual dysfunction, and possibly polycystic ovary syndrome (PCOS). Potential mechanisms for
these disturbances include disruption of the hypothalamic-pituitary-adrenal (HPA) axis via seizure discharges in limbic structures and/or AEDs. AEDs, particularly the enzyme-inducing agents (e.g., carbamazepine, phenytoin, and phenobarbital), also may affect HPA function by altering the metabolism of the neuroactive sex hormones, including testosterone. Although a causal relationship has not yet been established, there is an apparent increased incidence of PCOS in women with epilepsy who are receiving valproic acid.59

During pregnancy there may be increased maternal seizures, pregnancy complications, and adverse fetal outcome. Approximately 25% to 30% of pregnant women have increased seizures, whereas seizures decrease in a similar number. However, the risk of seizures is significantly less if the patient has been seizure free 12 months prior to the pregnancy.55 Increased seizure frequency may result from either a direct effect on seizure threshold or a reduction in AED concentration. An increase in clearance has been reported for phenytoin, carbamazepine, phenobarbital, ethosuximide, lamotrigine, oxcarbazepine, levetiracetam, topiramate, and clorazepate during pregnancy. Protein binding may also be reduced. The altered disposition of AEDs can begin as early as the first 10 weeks of pregnancy, and may require up to 4 weeks postpartum to normalize (longer for carbamazepine and phenobarbital than for phenytoin).

Women with epilepsy have a higher incidence of adverse pregnancy outcomes. Although the risk of congenital malformations is 4% to 6% (twice as high as in nonepileptic women), more than 90% of pregnancies in epileptic mothers have satisfactory outcomes. Older data, much of which included AED polytherapy, indicated that barbiturates and phenytoin may cause congenital heart malformations, orofacial clefts, and other malformations. From these data the risk of neural tube defect with valproic acid and carbamazepine has been estimated to be 0.5% to 1%, respectively, and appears to be related to drug exposure during gestational days 0 to 28. Other adverse pregnancy outcomes associated with maternal seizures, but not necessarily caused by AEDs, are growth, psychomotor, and mental retardation. Women with epilepsy are also more likely to have miscarriages, and 10% to 20% of infants are born with low birth weight. Updated practice parameters are available to aid in the counseling and management of pregnant women with epilepsy.52-54

Some teratogenic effects may be prevented by adequate folate intake; therefore, prenatal vitamins with folic acid (0.4–5 mg/day) should be given to any woman of child-bearing potential who is taking AEDs.56 Higher folate doses should be used in women with a history of a previous pregnancy with a neural tube defect or taking valproic acid. Higher AED doses and serum concentrations, polytherapy, and a family history of birth defects appear to increase the teratogenic risk of AEDs. Deciding on the most effective single-drug treatment prior to conception is vitally important. New AEDs are reported to be less teratogenic, and animal reproductive toxicology studies appear to be favorable. At present, clinical data are still limited, and more experience is needed before the true risk (or lack thereof) can be determined. However, multiple registries worldwide are collecting prospective data on pregnancy outcomes in users of newer and older AEDs. To date, results indicate that valproic acid mono- as well as polytherapy is associated with a significantly higher rate of fetal malformations compared to the other AEDs, especially at doses greater than 1,400 mg/day.55 Some AEDs can cause neonatal hemorrhagic disorder, which can be prevented by administering 10 mg/day vitamin K orally to the mother during the last month of pregnancy and/or administering parenteral vitamin K to the newborn at delivery.64

Most AEDs pass into the breast milk, and concentrations are measurable in breastfeeding infants. In general, the degree of protein binding of a given AED allows for prediction of its concentration in breast milk. AEDs with less protein binding accumulate more in breast milk. Treatment with AEDs is not necessarily a reason to discourage breastfeeding. In fact, an argument could be made that since AEDs should rarely be discontinued abruptly, breastfeeding is a reasonable way to allow for a downward titration of a medication that the baby was exposed to for the past 9 months. Infants born to women taking any AED (particularly barbiturates or benzodiazepines) should be closely observed for signs of excess sedation, irritability, or poor feeding.60

The perimenopausal period can be associated with worsening of seizures. At menopause, seizures often improve in frequency, particularly in women with a catamenial seizure pattern. The effect of hormone replacement therapy on seizure control is still unclear, but clinicians should monitor for seizure exacerbation in women receiving supplemental estrogen. Exacerbation of seizures has been noted in postmenopausal women on lamotrigine taking hormone replacement therapy.57 Data suggest that men with epilepsy have reduced fertility, and that carbamazepine, oxcarbazepine, and valproic acid are associated with sperm abnormalities in these men. In addition, valproic acid seems to cause testicular atrophy resulting in reduced testosterone volume.59

### CLINICAL CONSIDERATIONS WITH SPECIFIC DRUGS

#### Tables 65–4 through 65–8 list specific data (including pharmacokinetics, adverse effects, AED interactions, metabolism, and dosing) for each of the commonly used AEDs. Below we summarize the pharmacology, advantages and disadvantages, and perspectives on the place in therapy of each AED.

**Carbamazepine**

**Pharmacology and Mechanism of Action** The exact mechanism by which carbamazepine suppresses seizure spread is obscure, however, it is believed to act primarily by enhancing fast inactivation of voltage-gated sodium channels. In addition, interaction with voltage-gated calcium and potassium channels might also contribute to its activity.59

**Pharmacokinetics** The absorption of carbamazepine from immediate-release tablets is slow and erratic because of its low water solubility. There is also large variability in the peak-to-trough concentrations of up to 40%. There is no first-pass metabolism. Food, especially fat, may enhance the bioavailability of carbamazepine. Carbamazepine suspension is absorbed faster than the tablets.59 Controlled-release (Tegretol-XR) and sustained-release (Carbatrol) preparations are also available, and they are bioequivalent in twice-daily (every 12 hours) dosing to immediate-release carbamazepine dosed 4 times daily (every 6 hours). Compared with immediate-release carbamazepine, both these formulations have lower peaks and higher troughs, which may decrease side effects and improve seizure control. Carbatrol can improve QOL measurements compared to the immediate-release product.71 Patients should be told to take Tegretol-XR with food and that the casing will be excreted in the feces. It cannot be broken or crushed. Tegretol-XR and Carbatrol appear to be bioequivalent; however, there is less variability in the absorption of Carbatrol.70

Carbamazepine is a neutral and highly lipophilic drug that is highly protein bound to α1-acid glycoprotein and albumin. The major metabolite is carbamazepine-10,11-epoxide, which has anticonvulsant activity in animals and humans.70 The formation of the 10,11-epoxide is influenced by concurrent use of other enzyme-inducing or enzyme-inhibiting drugs; thus the 10,11-epoxide concentration may change with the administration of other drugs (e.g., valproate and felbamate) without change in parent carbamazepine concentration.70
Carbamazepine induces its own metabolism (autoinduction), thereby decreasing its half-life after chronic therapy.70 The presence of enzyme-inducing drugs reduces the half-life even more. The autoinduction effect begins within 3 to 5 days of starting therapy and takes 21 to 28 days to complete. Therefore, it is possible to achieve initial concentrations that are within the therapeutic range but have concentrations fall despite continued therapy and good compliance. Some patients who respond well to initial therapy may be labeled refractory or noncompliant if the autoinduction phenomenon is not considered. The autoinduction reverses rapidly if carbamazepine is discontinued. Carbamazepine also displays diurnal variation in its serum level with evening levels lower than morning levels.

**Adverse Effects** Carbamazepine side effects can parallel the rise and decline of serum concentrations daily. Neurosensory side effects (e.g., diplopia, blurred vision, nystagmus, ataxia, unsteadiness, dizziness, and headache) are the most common (35%–50% of patients). These side effects are more common during initiation of therapy and can dissipate with continued treatment. Carbamazepine can also cause nausea, which can be caused by a local effect of the drug on the GI tract, in which case food may help, or be caused by an effect on the brainstem, which may ultimately require discontinuation of the drug. Dosage manipulation, including the use of the controlled- or sustained-release preparations, should be tried before the patient is considered to be intolerant of carbamazepine. Carbamazepine can cause hyponatremia, the incidence of which increases with age, however, its occurrence is lower than that seen with oxcarbazepine. Periodic determinations of serum sodium concentration are recommended, especially in the elderly. 70

Leukopenia is the most common hematologic side effect, with an incidence as high as 10%. It usually is transient, even when the drug is continued, and can be caused by a redistribution of white blood cells (WBCs) rather than a decrease in their production. In about 2% of patients, leukopenia is persistent, but even patients with WBC counts of 3,000/mm$^3$ (3 × 10$^9$/L) or less do not seem to have an increased incidence of infection. A clinical guide is to continue carbamazepine therapy unless the WBC count drops to less than 2,500/mm$^3$ (2.5 × 10$^9$/L) and the absolute neutrophil count drops to less than 1,000/mm$^3$ (1 × 10$^9$/L).

**Drug Interactions** Because of concentration-dependent efficacy and side effects, drug interactions with carbamazepine often are very significant. Drugs that inhibit CYP3A4 potentially may increase carbamazepine serum concentrations. Carbamazepine can induce the metabolism of other drugs.

**Dosing and Administration** The variable contributions of the 10,11-epoxide metabolite and free-carbamazepine concentrations have restricted a precise definition of the therapeutic range.

**Notes:** IM, intramuscular; LD, loading does; MHD, 10-monohydroxy-derivative; PO, orally; VPA, valproic acid.

**Data from:** Sessions et al.,70 Talbot and Laposata,52 Cadis et al.,54 and Sabel [package insert].55
Metabolism occurs in the liver by hydroxylation of carbamazepine, which is a substrate of the liver microsomal cytochrome P450 enzyme system. Other drugs can interact with carbamazepine metabolism, and it is necessary to administer the drug two to four times per day. Carbamazepine tablets should not be stored in places where they would be exposed to high heat and high humidity.

**Advantages** Carbamazepine has been well studied. Oral solid and liquid dosage forms are available. The oral solid dosage form is available as an immediate-release tablet, as a sustained-release capsule, and a controlled-release tablet. The sustained- and controlled-release dosage forms allow for twice-daily dosing to reduce the peak-to-trough fluctuations. Compared with other first-generation AEDs, carbamazepine causes minimal cognitive impairment.

**Disadvantages** Carbamazepine has an active metabolite that can contribute to efficacy and toxicity. Other drugs can alter the concentration of this metabolite without changing the concentration of the parent carbamazepine. It induces its own metabolism, which complicates dosage titration. It also induces the metabolism of other medications, and other drugs may interact with it and/or its active metabolite. There is no parenteral formulation. There are clinically meaningful CNS side effects including sedation and nausea. One prospective study, however, found fewer side effects with the sustained-release formulation compared to the immediate-release formulation. When ingested during the first trimester of pregnancy, carbamazepine has been associated with a 1% risk of spina bifida. Chronic carbamazepine use has also been associated with decreases in bone mineral density and 25-hydroxy(OH) vitamin D. The generic formulations of immediate-release tablets have been associated with breakthrough seizures when brands have been switched.

**Place in Therapy** Carbamazepine is considered a first-line therapy for patients with newly diagnosed partial seizures and for patients with primary generalized convulsive seizures who are not responsive to other AEDs. It should be reserved for patients not responding to other AEDs.

**Ethosuximide**

**Pharmacology and Mechanism of Action** Ethosuximide is believed to exert its primary action through inhibition of T-type calcium channels.

**Pharmacokinetics** Metabolism occurs in the liver by hydroxylation, and the metabolites are believed to be inactive. There is some evidence of nonlinear pharmacokinetics at higher concentrations.

**Adverse Effects** The most frequently reported side effects are nausea and vomiting (up to 40%), which may be minimized by administration of smaller doses and more frequent dosing.

**Drug Interactions** Because ethosuximide is not protein bound, displacement interactions do not occur. Valproic acid may inhibit the metabolism of ethosuximide, but only if the metabolism of ethosuximide is near saturation.

**Dosing and Administration** A loading dose is not required. Titration over 1 to 2 weeks to maintenance doses of 20 mg/kg per day usually results in therapeutic concentrations. Data suggest that patients can be managed successfully on once-a-day therapy; however, gastrointestinal (GI) distress appears to be dose related, and the total daily dose is usually divided into two equal doses.

**Advantages** This drug is very effective in the treatment of absence seizures. It is generally well tolerated and has few pharmacokinetic interactions.

**Disadvantages** Ethosuximide has a very narrow spectrum of activity.

**Place in Therapy** Ethosuximide is still a first-line treatment for absence seizures.

**Felbamate**

**Pharmacology and Mechanism of Action** At therapeutic doses, felbamate appears to act by blocking N-methyl-D-aspartate (NMDA) synaptic responses and by modulating GABA_A receptors. At higher doses it may modulate sodium channels and inhibit high-voltage activated calcium channels.

**Pharmacokinetics** Felbamate is rapidly and well absorbed. The absorption is unaffected by food or antacids. Approximately 40% to 50% of a dose of felbamate is metabolized by hydroxylation and conjugation pathways in the liver, and the remainder is excreted unchanged in the urine. It displays linear pharmacokinetics.

**Adverse Effects** The most frequently reported side effects prior to marketing were anorexia, weight loss, insomnia, nausea, and headache (sometimes severe). Anorexia and weight loss may be especially problematic in children and in patients with diminished caloric intake. After marketing, felbamate was found to be associated with aplastic anemia and acute liver failure. The onset was between 68 and 354 days of therapy. The approximate rate of occurrence of aplastic anemia is 1 in 3,000 and of hepatitis is 1 in 10,000. Data suggest a possible increased risk for aplastic anemia in patients, especially women, with a history of cytopenia, AED allergy or significant toxicity, viral infection, and/or immunologic problems.

**Drug Interactions** Felbamate can induce or inhibit the metabolism of the older AEDs. Interactions between warfarin and felbamate have also been reported.

**Dosing and Administration** The initial starting dose of felbamate is increased at 2-week intervals.

**Advantages** Felbamate has a broad spectrum of activity and a unique mechanism of action. It is approved for treating atonic seizures in patients with the Lennox—Gastaut syndrome and is also effective in treating patients with partial seizures.

**Disadvantages** The use of felbamate is limited by the association with aplastic anemia and hepatotoxicity, as well as multiple drug interactions.

**Gabapentin**

**Pharmacology and Mechanism of Action** Gabapentin was designed to be a GABA agonist but does not react at the GABA receptor, alter GABA uptake, or interfere with GABA transaminase. Gabapentin appears to bind to an amino acid carrier protein and to act at a unique receptor. It inhibits high-voltage activated calcium channels. It elevates human brain GABA levels, possibly via alterations in GABA synthesis or reversal of the neuronal GABA transporter, resulting in nonvesicular release of GABA.

**Pharmacokinetics** Gabapentin is a substrate of the L-amino acid carrier protein in the gut (system L) and in the CNS. This carrier protein transports the drug across the gut membrane by an active process. The binding of gabapentin to this system is saturable, and gabapentin therefore displays dose-dependent bioavailability that appears to vary considerably between individuals. Food, including protein-rich meals, does not appear to interfere with gabapentin oral absorption. Concentrations in human CSF are 5% to 35% of plasma levels, and tissue concentrations are approximately 80% of plasma levels.

Because gabapentin is eliminated exclusively by the kidneys, dosage adjustments are necessary in patients with significantly impaired renal function.
**Adverse Effects** Fatigue, somnolence, dizziness, and ataxia are the most frequently reported side effects. Aggressive behavior has been reported in children. The CNS effects of gabapentin are generally less than those of traditional AEDs. A withdrawal reaction characterized by anxiety, insomnia, nausea, sweating, and increased pain has also been reported with abrupt discontinuation in patients taking it for pain.

**Drug Interactions** Gabapentin does not induce or inhibit liver enzymes; therefore, drug interactions are not likely to occur. There is a 10% reduction in the clearance of gabapentin in patients taking cimetidine and a 20% reduction in the bioavailability if aluminum antacids are taken simultaneously with gabapentin. These interactions are unlikely to be clinically significant.

**Dosing and Administration** Typical starting doses of gabapentin are 300 mg at bedtime on the first day, increasing to 900 mg/day over 3 days. Faster titration rates (e.g., starting at 300–900 mg 3 times daily) have been well tolerated. Data suggest gabapentin should be given at least 4 times a day when the total daily dose is 3,600 mg or greater. It does not appear to be absorbed rectally. Patients with end-stage renal disease maintained on hemodialysis should receive an initial 300- to 400-mg dose with 200 to 300 mg gabapentin given after every 4 hours of hemodialysis.

**Advantages** Gabapentin has multiple mechanisms of action and is mechanistically different from first-generation AEDs. It is not metabolized and is excreted unchanged by the kidney. It has a broad therapeutic index with minimal CNS adverse effects and few drug interactions. Doses can be escalated rapidly.

**Disadvantages** Gabapentin is absorbed by an active process that saturates at higher doses. This may require more frequent daily dosing for patients who need doses greater than 3,600 mg/day. Doses exceeding the 3,600 mg/day maximum listed in the package insert may be required in some patients to achieve seizure remission. There is no parenteral formulation.

**Place in Therapy** Gabapentin is a second-line agent for patients with partial seizures who have failed initial treatment. In addition, although monotherapy has no proven efficacy in previously diagnosed refractory patients, it may have a role in patients with less severe seizure disorders, such as new-onset partial epilepsy, particularly in the elderly. Gabapentin also has been shown to be useful for chronic pain and other nonepileptic conditions.

**Lacosamide**

**Pharmacology and Mechanism of Action** Lacosamide is a functionalized amino acid with unknown mechanism of action, but two mechanisms are suggested. It selectively enhances slow inactivation of voltage-gated sodium channels, resulting in stabilization of hyperexcitable neuronal membranes and inhibition of repetitive neuronal firings. In addition, it binds to collapsin response mediator protein (CRMP-2), a phosphoprotein mainly expressed in the CNS, and it is involved in neuronal differentiation and control of axonal outgrowth. The role of CRMP-2 binding in seizure control is unknown.

**Pharmacokinetics** Lacosamide is rapidly and almost completely absorbed after oral administration, and food does not affect its bioavailability. There is a linear relationship between daily doses and serum concentrations up to 800 mg/day. No dosage adjustment is necessary in children or the elderly. Moderate hepatic and renal impairment have both been shown to increase systemic drug exposure up to approximately 40%.

**Adverse Effects** The most frequent side effects of lacosamide are dose related, including dizziness, nausea, diplopia, abnormal coordination, ataxia, vomiting, and nystagmus. The drug can also cause a small increase in median PR interval (5–9 msec) on the ECG.

**Drug Interactions** The blood level of lacosamide is decreased by approximately 15% to 20% by enzyme-inducing AEDs. It is a substrate of CYP2C19; however, there are no known drug interactions between lacosamide and drugs metabolized by CYP2C19. The drug does not appear to affect the serum concentration of OCs containing ethinyl estradiol and levonorgestrel.

**Dosing and Administration** The starting dose is 100 mg/day in two divided doses, with dose increase by 100 mg/day every week until a daily dose of 200 to 400 mg has been reached. Studies have shown that a dose of 600 mg daily may be efficacious for some patients, but at the expense of more CNS side effects.

**Advantages** There is an intravenous form of lacosamide available for short-term replacement that appears to be safe, well tolerated, and easy to administer. It does not affect the serum level of other AEDs, and its serum level is minimally affected by enzyme-inducing AEDs. It has novel mechanism(s) of action.

**Disadvantages** Lacosamide is a controlled substance class V.

**Place in Therapy** It is a potent second-line agent that should be considered in those patients who have failed first-line AEDs.

**Lamotrigine**

**Pharmacology and Mechanism of Action** A primary mechanism of action for lamotrigine appears to be inhibition of voltage-dependent sodium channels; however, it also inhibits high voltage-activated calcium channels and attenuates release of glutamate and to a lesser extent, GABA and dopamine.

**Pharmacokinetics** Lamotrigine is completely and rapidly absorbed, with a bioavailability of 98%. Food does not significantly affect absorption. It is also absorbed following rectal administration, but the bioavailability is approximately 50% of that of oral dosage forms. Lamotrigine clearance is higher in children and lower in the elderly compared with young adults. There are only modest differences in the pharmacokinetics of lamotrigine in the elderly versus younger subjects. Hepatic disease, depending on severity, can influence lamotrigine pharmacokinetics. Approximately 17% of a lamotrigine dose can be removed by hemodialysis, with the half-life being reduced to approximately 13 hours. For patients on dialysis, the half-life is much more prolonged between dialyses (57.4 hours). The half-life is prolonged in patients with renal failure.

**Adverse Effects** The most frequently reported side effects of lamotrigine include diplopia, drowsiness, ataxia, and headache. Adverse effects are more common when lamotrigine is given in combination with other AEDs (e.g., diplopia when given concomitantly with carbamazepine or tremor with valproic acid) compared with monotherapy, and they can be pharmacodynamic in nature. Lamotrigine can cause rash, which usually appears in the first 3 to 4 weeks of therapy. Patients who have developed a rash with another AED are more likely to develop a rash with lamotrigine. The rash typically is generalized, erythematous, and morbilliform. However, a Stevens—Johnson reaction also has been reported. Some rashes, especially those which develop early, can necessitate the withdrawal of lamotrigine. Risk factors for the emergence of more serious rashes appear to be concomitant use of valproic acid and situations where high initial doses or rapid dosage escalation is used. Data from several European monotherapy trials suggest that when dosed appropriately, the incidence of rash from lamotrigine is similar to that of older agents such as carbamazepine and phenytoin. The incidence is higher in children than in adults.

**Drug Interactions** Lamotrigine does not inhibit liver enzymes and has a low potential for pharmacokinetic interactions with other drugs. It has been found to decrease the bioavailability of the progesterone component (levonorgestrel) of a combination OC by 19%. The clinical relevance of this interaction has not been determined.
Concomitant treatment with OCs can lead to a reduction in the serum concentrations of lamotrigine because of an induction of lamotrigine glucuronidation by ethinyl estradiol. In addition lamotrigine serum levels can significantly increase during the week off OC treatment in some patients. Valproic acid substantially inhibits the metabolism of lamotrigine, with maximal inhibition occurring at valproic acid doses and serum concentrations of 500 mg/day and 40 to 50 mcg/mL (280–350 μmol/L), respectively. A pharmacodynamic interaction can occur with concurrent carbamazepine therapy, causing an increase in CNS side effects.

Dosing and Administration In patients who are taking enzyme-inducing drugs, lamotrigine can be started more rapidly than in patients receiving valproic acid. The maintenance doses are also different. Managing dosing is critical owing to the relationship between rash, concomitant valproic acid treatment, and the dose escalation rate. Removal of inducers from a lamotrigine regimen may necessitate decreases in lamotrigine dose, whereas removal of valproic acid can necessitate an increase in the lamotrigine dose. A dispersible and oral disintegrating tablet are available for patients who cannot swallow an oral solid tablet.

Advantages Lamotrigine is potentially a broad-spectrum AED, having efficacy in partial seizures and several types of generalized seizures. Pediatric dosage forms are available as a chewable dispersable tablet and an oral disintegrating tablet. It neither induces nor inhibits the metabolism of other AEDs. Lamotrigine has linear pharmacokinetics and is not highly protein bound. It is generally well tolerated in both children and elderly patients and does not cause weight gain.

Disadvantages Lamotrigine is associated with rash, especially in patients who start at a high dose, have rapid dose escalation, and/or are taking concurrent valproic acid. Therefore, the initial doses must be low (especially if the patient is on valproic acid) and escalated slowly to maximize safety. There is no parenteral dosage form.

Place in Therapy Lamotrigine is useful as both adjunctive treatment in patients with partial seizures and as monotherapy. Lamotrigine monotherapy appears to have comparable effectiveness with more traditional AEDs such as carbamazepine and phenytoin. In addition, it may be a useful alternative for primary generalized seizure types such as absence and as adjunctive therapy for primary GTC seizures, the latter of which is an approved indication.

Levetiracetam
Pharmacology and Mechanism of Action Levetiracetam is chemically unrelated to other AEDs. Although the mechanism of action of levetiracetam has yet to be delineated, it is known that this drug is not active in the classic models used to test AEDs. The drug binds in the brain to the synaptic vesicle protein SV2A, which is believed to be important in its activity. This agent may have a unique mechanism of action. Limited animal data suggest that levetiracetam may have antiepileptogenic effects, meaning that it may prevent the development of epilepsy under certain circumstances, however confirmation of this research is needed.

Pharmacokinetics Absorption of levetiracetam is rapid and complete following oral administration, and it is not significantly affected by food or enteral nutrition formulas. Renal elimination of unchanged parent drug accounts for the majority of clearance (66%), with the remainder being metabolized via nonhepatic enzymatic hydrolysis to inactive metabolites. This pathway involves neither the CYP450 or UGT isozyme systems. Because it is eliminated renally, clinicians should anticipate age-related reductions in clearance in elderly patients. Conversely, levetiracetam clearance appears to be approximately 40% higher in children than in adults. In addition, patients with severe liver cirrhosis should initially receive one-half the recommended starting dose because of a 57% decrease in clearance. Levetiracetam is excreted into breast milk in potentially clinically important amounts. Data are sparse regarding serum concentration—effect relationships, so the role of therapeutic drug level monitoring remains unclear.

Adverse Effects Adverse effects appear to be modest, with sedation, fatigue, and coordination difficulties being the most common CNS effects. In children and young adults, agitation, irritability or somnolence/lethargy are the most frequently reported CNS side effects. The mechanism underlying these effects is unknown. Formal studies evaluating the cognitive effects of this medication have not yet been conducted.

Drug Interactions Levetiracetam neither inhibits nor induces the CYP450, UGT, or epoxide hydrolase enzyme systems, and in vitro data predict a low potential for pharmacokinetic interactions. It does not appear to interact with other AEDs, warfarin, digoxin, or oral contraceptive drugs.

Dosing and Administration Levetiracetam is available orally and parenterally, the latter for maintenance dosing only. The intravenous (IV) product has not been tested for intramuscular (IM) use, and therefore, should not be administered IM. Typically the initial dose is given twice daily, with dosage increments every 2 weeks. To minimize CNS side effects, dosing may be initiated at one-half this rate. The IV formulation should be given at the same frequency and dose as the oral product. Although not FDA approved, the oral dose of levetiracetam has been titrated up rapidly to 3,000 mg in 3 days in some intractable seizure patients with improvement seen after day 2.

Advantages Levetiracetam is felt to have a novel, although unknown, mechanism of action. It has linear pharmacokinetics and is not metabolized by the cytochrome P450 system. No significant drug interactions, including with OCs, have been reported. Initial doses may be effective. The drug appears to be well tolerated, with transient sedation being the most troublesome adverse effect.

Disadvantages Dose adjustments are needed for patients with decreased renal function, and slower dose escalation may be needed to avoid CNS adverse effects. Behavioral problems can limit therapy in some patients.

Place in Therapy Levetiracetam is indicated for patients with partial seizures who have failed initial therapy. Its role as monotherapy for partial seizures remains to be clarified. It is approved for adjunctive treatment of myoclonic seizures in patients with JME and as adjunctive treatment of primarily generalized seizures in patients with idiopathic generalized epilepsy.

Oxcarbazepine
Pharmacology and Mechanism of Action Oxcarbazepine, which is structurally related to carbamazepine, is a prodrug that is rapidly converted to the active 10-monoxydorboxy derivative (MHD). The mechanism of action of oxcarbazepine is similar to that of carbamazepine. Oxcarbazepine and MHD block voltage-sensitive sodium channels, modulate the voltage-activated calcium currents, and increase potassium conductance. Interestingly, however, oxcarbazepine can display differing affinities for both sodium channels and Ca2+ channels compared with older drugs such as carbamazepine. Whereas carbamazepine may modulate L-type Ca2+ channels, oxcarbazepine appears to modulate N- and P-type Ca2+ channels. Whether these differences lead to differing patterns of clinical effectiveness is uncertain. It has no significant interactions with neurotransmitters or modulation of receptor sites.

Pharmacokinetics Oxcarbazepine is absorbed completely, and MHD is inactivated by glucuronide conjugation and eliminated by the kidneys. Oxcarbazepine and its active metabolite do
neurologic disorders

who develop a rash with carbamazepine will experience a similar effect with oxcarbazepine, and they should instruct patients regarding the need for monitoring serum sodium levels following the initiation of oxcarbazepine treatment. Hyponatremia appears to occur less frequently in children. Clinicians should be particularly watchful in patients receiving concomitant sodium-depleting drugs such as diuretics. Hyponatremia may be more common in elderly patients than in young adults. CNS adverse effects appear to be far more common at doses greater than 1,200 mg/day. Hyponatremia, defined as a plasma sodium concentration of less than 125 mmol/L, has been reported in up to 25% of patients taking oxcarbazepine and occurs more often in elderly patients. Clinicians should be particularly watchful in patients receiving concomitant sodium-depleting drugs such as diuretics. Hyponatremia appears to occur less frequently in children. Clinicians should consider monitoring serum sodium levels following the initiation of oxcarbazepine, and they should instruct patients regarding the symptoms of hyponatremia. Approximately 25% to 30% of patients who develop a rash with carbamazepine will experience a similar reaction with oxcarbazepine. The tolerability of oxcarbazepine has not been compared with that of extended-release formulations of carbamazepine that have lower peaks and potentially fewer side effects than immediate-release carbamazepine formulations.

**Drug Interactions** Oxcarbazepine decreases the bioavailability of ethinyl estradiol and levonorgestrel. Women concurrently taking OCs should be counseled about the potential for contraceptive failure. Unlike carbamazepine, there are no interactions between cimetidine, erythromycin, or warfarin and oxcarbazepine. The administration of oxcarbazepine in doses greater than 1,200 mg with phenytoin has resulted in a 40% increase in the concentration of phenytoin, consistent with inhibition of CYP450 2C19. Oxcarbazepine treatment may modestly reduce lamotrigine serum concentrations, suggesting induction of UGT isozymes.

The replacement of carbamazepine with oxcarbazepine may result in a drug interaction because an enzyme-inducing drug is being removed.

**Dosing and Administration** Doses and titration schedules differ regarding whether the drug is used for mono- or adjunctive therapy in adults vs children. Although not FDA approved, doses up to 60 mg/kg/day have been used in infants and children younger than 4 years of age to successfully control partial-onset seizures. In patients being converted from carbamazepine, the typical maintenance dose of oxcarbazepine is 1.5 times the carbamazepine dose or less, if patients are on large doses of carbamazepine, due to auto-induction of carbamazepine but not oxcarbazepine.

**Advantages** The efficacy of oxcarbazepine is comparable with that of carbamazepine, phenytoin, and valproic acid. It may be better tolerated than phenytoin as monotherapy and therefore, less likely to be discontinued. There is broad international experience with this drug.

**Disadvantages** About 30% of patients who have experienced a rash with carbamazepine have a cross-reaction with oxcarbazepine. There are more reports of hyponatremia with oxcarbazepine, especially in patients at risk. Replacing carbamazepine with oxcarbazepine can result in interactions owing to the removal of an enzyme inducer. Enzyme-inducing drugs can increase the clearance of MHD.

**Place in Therapy** Oxcarbazepine is indicated for use as monotherapy or adjunctive therapy in the treatment of partial seizures in adults and children as young as 4 years of age. It is also a potential first-line drug for patients with primary generalized convulsive seizures. Oxcarbazepine may also be effective in patients not demonstrating a response to carbamazepine.

**Phenobarbital**

**Pharmacology and Mechanism of Action** Phenobarbital may elevate seizure threshold by interacting with GABA receptors to facilitate intrinsic chloride channel function, by blocking high voltage-activated calcium channels, and by blocking a-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate receptors.

**Pharmacokinetics** Phenobarbital is absorbed rapidly and completely regardless of whether it is given orally, intramuscularly, or rectally. It penetrates the brain at a rate comparable with that of phenytoin, and peak concentrations are achieved 3 to 20 minutes after an IV dose.

Drugs affecting liver enzymes can alter phenobarbital metabolism, but phenobarbital clearance is not affected by liver blood flow. The elimination of phenobarbital is linear. Because tubular reabsorption of phenobarbital is pH dependent, the amount excreted renally can be increased by giving diuretics and urinary alkalinizers. Clearance decreases in the elderly.

**Adverse Effects** CNS side effects are the primary factors limiting the use of phenobarbital. Tolerance usually develops to initial complaints of fatigue, drowsiness, sedation, and depression. In children, paradoxically, the primary side effect is hyperactivity. It may also cause porphyria and rash, including serious rashes such as Stevens—Johnson syndrome.

**Drug Interactions** Phenobarbital is a potent enzyme inducer and can increase the elimination of any drug metabolized by CYP450 or UGT-mediated metabolism. Cimetidine and chloramphenicol inhibit phenobarbital metabolism, necessitating a decrease in dose. Ethanol increases the metabolism of phenobarbital.

**Dosing and Administration** In nonacute situations, phenobarbital should be started in low doses and titrated upward. The dose-concentration relationship is linear. Because the half-life of phenobarbital is long, doses can be given once daily, and bedtime dosing may minimize CNS depression.

**Advantages** Phenobarbital has linear and predictable pharmacokinetics. Multiple dosage forms (e.g., oral solid, oral liquid, IM, and IV) are available, and it is the most inexpensive AED.

**Disadvantages** Phenobarbital has significant side effects, including delayed intellectual development and hyperactivity in children and significant cognitive impairment in adults. It is an enzyme inducer and interacts with many other drugs metabolized by the cytochrome P450 system. Phenobarbital has a very long half-life, and dosage adjustments should not be made more often than every 2 to 3 weeks. The parenteral product contains 67% to 75% propylene glycol and 10% alcohol, which can result in significant respiratory depression and hypotension if infused too rapidly.

**Place in Therapy** Phenobarbital is the drug of choice for neonatal seizures but in other situations is reserved for patients who have failed therapy with other AEDs. It may be useful given IV in refractory status epilepticus.

**Phenytoin**

**Pharmacology and Mechanism of Action** The primary mechanism of action of phenytoin is believed to be its ability to inhibit voltage-dependent sodium channels.
Pharmacokinetics  The pharmacokinetics of phenytoin are complex. For a more in-depth understanding, the reader is referred to a more extensive review. The oral absorption of phenytoin is almost complete. Dissolution is the rate-limiting step, and absorption may be saturable at higher doses, such as those used for oral loading. Absorption following IM administration of phenytoin is erratic and delayed, and IM injections are painful; however, IM absorption following fosphenytoin is rapid and well tolerated.

Phenytoin enters the brain rapidly and is redistributed to other body tissues, including breast milk and the placenta. Phenytoin competes for albumin sites with other highly protein-bound drugs. It is essential to know the patient’s serum albumin level in interpreting the serum concentrations of phenytoin. Patients with significant renal dysfunction will have altered phenytoin protein binding. Obesity increases the volume of distribution.

Phenytoin is metabolized in the liver by parahydroxylation. The major isoforms responsible for the metabolism of phenytoin are CYP2C9 and CYP2C19; the former displays polymorphism, which may affect the response to phenytoin. Phenytoin displays Michaelis—Menten pharmacokinetics, and the metabolism of phenytoin saturates at doses used clinically. The clinical importance of this is that a small change in dose can result in a disproportionately large increase in serum concentrations, potentially leading to toxicity. In some patients the metabolism of phenytoin can saturate even at low serum concentrations within the therapeutic range. The long held belief that the metabolism of phenytoin decreases with age in adults has recently been challenged.

Adverse Effects  When phenytoin is initiated, the CNS depressant effects include lethargy, fatigue, incoordination, blurred vision, higher cortical dysfunction, and drowsiness. These effects usually are transient and can be minimized by slow dosage titration. At very high concentrations of greater than 50 mcg/mL (200 μmol/L), phenytoin can exacerbate seizures.

It is unclear whether the chronic side effects of phenytoin are concentration or duration dependent. One of the more common chronic side effects is gingival hyperplasia. Good oral hygiene can minimize gingival hyperplasia and should be encouraged. Other chronic effects include vitamin D deficiency, osteomalacia, carbohydrate intolerance, immunologic disturbances, hypothyroidism, and peripheral neuropathy. Phenytoin is associated with rare hypersensitivity or idiosyncratic reactions resulting in rashes, Stevens—Johnson syndrome, pseudolymphoma, bone marrow suppression, lupus-like reactions, and hepatitis.

Drug Interactions  Phenytoin is associated with numerous drug interactions involving altered absorption, metabolism, and protein binding that can enhance or reduce its effects. It is an inducer of both CYP450 and UGT isozymes. The absorption of phenytoin can be increased or decreased with the administration of food depending on the composition of the meal. The bioavailability of phenytoin suspension can be decreased in patients receiving continuous enteral nutrient tube feedings. However, a single-dose study of simultaneous administration of enteral feeding found no difference in phenytoin bioavailability, suggesting that the mechanism was something other than physical contact.

Phenytoin decreases folic acid absorption. Replacement of folic acid can reduce phenytoin concentration and result in loss of efficacy.

Dosing and Administration  Four oral dosage forms are available, and changing dosage forms can lead to changes in phenytoin serum concentrations. Whether or not a dosage form uses the parent drug or salt form should be considered when changing from one dosage form to another. One hundred milligrams of phenytoin acid is equal to 92 mg of phenytoin sodium. Phenytoin capsules are designated as immediate-release or extended-release. Only the extended-release capsules should be used in once-daily dosing.

Particle size rather than formulation may determine the rate of absorption.

If oral administration is not feasible, IV administration of phenytoin is preferred, as IM administration can cause tissue necrosis. Fosphenytoin is a prodrug for phenytoin and is available as a parenteral dosage form. Fosphenytoin is ordered in phenytoin equivalents (PE), the actual dose of phenytoin acid desired. It is very water-soluble and is converted rapidly to phenytoin systemically. Fosphenytoin can be given rapidly intravenously and intramuscularly with reliable absorption and minimal pain. It is significantly better tolerated than phenytoin.

Because of saturable absorption, an oral loading dose, such as 20 mg/kg, should be divided into four equal doses and given at 6-hour intervals. Subsequent dosage adjustments should be done cautiously owing to its nonlinear elimination. One author has suggested that if the serum concentration is less than 7 mcg/mL (28 μmol/L), the daily dose should be increased by 100 mg; if the serum concentration is between 7 and 12 mcg/mL (28 and 48 μmol/L), the daily dose can be increased by 50 mg; and if the serum concentration is greater than 12 mcg/mL (48 μmol/L), the daily dose can be increased by 30 mg or less. These increases are reported to result in less than 10% of patients achieving a phenytoin serum concentration greater than 25 mcg/mL (99 μmol/L).

Advantages  After more than 65 years, its risk-to-benefit ratio is well established. It is available in oral solid, oral liquid, extended-release oral solid, and parenteral (phenytoin and fosphenytoin) dosage forms, allowing flexibility in dosing and use in emergent situations. In some patients, the extended-release dosage form can be given once a day with good seizure control.

Disadvantages  Phenytoin displays Michaelis—Menten pharmacokinetics, meaning that the metabolism saturates at doses given clinically thus complicating dose titration. Also, phenytoin is an inducer of cytochrome P450 enzymes, is metabolized by cytochrome P450 enzymes, and is highly protein bound. Therefore, many drug interactions are associated with coadministration of this agent. It also has multiple significant adverse effects.

Place in Therapy  Phenytoin has long been a first-line AED for primary generalized convulsive and partial seizures. However, its place in therapy may be reevaluated as more experience is gained with newer AEDs.

Pregabalin  Pharmacology and Mechanism of Action  Pregabalin’s mechanism of action is unknown, however, it is proposed that its binding to the subunit of the voltage-gated calcium channel may be responsible for a large part of its activity. This binding results in a decrease in the release of several excitatory neurotransmitters including glutamate, noradrenaline, substance P, and calcitonin gene-related peptide.

Pharmacokinetics  Pregabalin is a substrate of the L-amino acid carrier protein in the CNS. It does not display dose-dependent bioavailability. Food decreases the rate of absorption but not the bioavailability of the drug.

Pregabalin is eliminated primarily by renal excretion as an unchanged drug, and therefore dosage adjustment is required in patients with significantly impaired renal function. In anuric patients, 50% of the dose is removed by 4 hours of hemodialysis.

Adverse Effects  Dizziness, somnolence, ataxia, blurred vision, and weight gain are the most frequently reported side effects. It is unknown if pregabalin causes aggressive behavior in children. A withdrawal reaction characterized by anxiety, nervousness, and irritability has been noted in patients being treated for generalized anxiety upon abrupt discontinuation of the drug.
**Drug Interactions**  Because pregabalin is predominantly excreted unchanged in the urine and undergoes negligible metabolism, drug interactions are unlikely.

**Dosing and Administration**  Starting doses of pregabalin are divided into twice or thrice daily intervals. The manufacturer recommends that patients with end-stage renal disease maintained on hemodialysis receive a 25 to 75 mg daily dose with 25 to 75 mg given after every 4 hours of hemodialysis.

**Advantages**  Pregabalin is somewhat more potent than gabapentin without the dose-limited GI absorption properties. It has minimal CNS side effects and no drug interactions.

**Disadvantages**  It is a controlled substance class V. Like gabapentin it can cause weight gain and peripheral edema, especially as the dose is increased. There is no parenteral formulation available.

**Place in Therapy**  Pregabalin is a second-line agent for patients with partial seizures who have failed initial treatment. It is also useful for chronic neuropathic pain and generalized anxiety disorder.

**Rufinamide**

**Pharmacology and Mechanism of Action**  Rufinamide is a triazole derivative structurally unlike any other AED. It suppresses neuronal hyperexcitability through prolongation of the inactivation phase of voltage-gated sodium channels.

**Pharmacokinetics**  Oral absorption is relatively slow with a \( t_{\text{max}} \) of 4 to 6 hours. At low doses (600 mg), the drug is relatively well absorbed (85%) when taken with food; however, the percentage of drug absorbed decreases with higher doses. Twice-daily dosing is recommended due to the slow absorption properties and the drug’s short half-life (6–10 hours). It is extensively metabolized with no active metabolites, with primary biotransformation by carboxylesterases. Although clinical data indicate that children and adults have similar pharmacokinetics, population pharmacokinetic modeling suggests that in the absence of interacting co-medication the drug may have a higher clearance in children.

**Adverse Effects**  The most common adverse effects include headache, dizziness, fatigue, somnolence, and nausea. These effects are dose dependent. Rufinamide may increase the incidence of convulsions in some patients, and may precipitate SE. Multiorgan hypersensitivity has occurred within 4 weeks of starting treatment in patients younger than 12 years of age.

**Drug Interactions**  Rufinamide is a weak inhibitor of CYP2E1 and a weak inducer of CYP3A4; the later effect may be responsible for modestly lower levels of carbamazepine and triazolam when given concomitantly with rufinamide. It may decrease the area under the curve of combination OCs containing ethinyl estradiol and norethindrone; however, it is not known if this is due to induction of CYP3A4 or uridine disphosphate glucuronosyl transferase (UDP-GT), or both. Rufinamide is responsible for a modest increase in the clearance of lamotrigine, phenobarbital, and phenytoin, and the effect is greater in children than adults. Carbamazepine, phenytoin, primidone, and phenobarbital significantly increase the clearance of rufinamide; however, it is believed this interaction is not entirely due to CYP450 enzyme induction. Valproic acid significantly decreases the clearance of rufinamide and elevates serum levels of rufinamide by 70%.

**Dosing and Administration**  The initial dose of rufinamide is 400 to 800 mg/day given in divided doses with an increase in dose every other day until a maximum dose of 45 mg/kg/day or 3,200 mg/day (which ever is less) is obtained.

**Advantages**  The drug is effective for seizures associated with Lennox—Gastaut syndrome without causing cognitive and psychiatric adverse effects. The dose can be rapidly escalated.

**Disadvantages**  Drug interactions are common with rufinamide, and patients with Lennox—Gastaut are usually on multiple medications. It displays decreased absorption at higher doses and when taken on an empty stomach. The drug has caused convulsions and SE in some patients.

**Place in Therapy**  As an adjunctive agent in controlling seizures in Lennox—Gastaut syndrome after patients have failed valproic acid, topiramate, and lamotrigine.

**Tiagabine**

**Pharmacology and Mechanism of Action**  Tiagabine is a potent and specific inhibitor of GABA uptake into neuronal elements, thus, enhancing the action of GABA by decreasing its removal from the synaptic space.

**Pharmacokinetics**  Tiagabine is absorbed quickly and nearly completely after oral administration. There is a linear relationship between dose and serum concentrations. Children eliminate tiagabine slightly faster than adults. Hepatic impairment causes higher and more prolonged plasma concentrations of total and unbound drug. Renal dysfunction does not change its pharmacokinetics. Tiagabine displays diurnal elimination, i.e., lower evening serum levels compared with morning levels.

**Adverse Effects**  The most frequently reported adverse effects of tiagabine are dizziness, asthenia, nervousness, tremor, diarrhea, and depression. Adverse events usually are mild to moderate and transient, and most occur during dose titration. CNS side effects can be diminished by taking tiagabine with food, thus slowing the absorption rate. It has increased the incidence of nonconvulsive SE in patients with chronic refractory partial epilepsy. In addition, there are reports of SE or new onset seizures occurring in patients without a history of epilepsy.

**Drug Interactions**  Food decreases the rate but not the extent of absorption. Tiagabine is displaced from protein by naproxen, salicylates, and valproate. However, tiagabine does not displace phenytoin, valproic acid, amitriptyline, tolbutamide, or warfarin.

**Dosing and Administration**  A clear dose-response has been demonstrated, and the minimal effective adult dose level is 30 mg/day. The initial dose is increased weekly.

**Advantages**  Tiagabine has a known mechanism of action. It is the first drug marketed in the United States that acts only on GABA receptors. It has linear pharmacokinetics and is not reported to interact with other drugs.

**Disadvantages**  Initially high and rapid dosage escalation is associated with increased CNS side effects. Therefore, the drug must be started at a low dose and titrated gradually to response. Lower doses may be needed in patients with liver disease. Tiagabine is metabolized by CYP450 3A4 enzymes, and other drugs may alter its clearance. There is no parenteral formulation.

**Place in Therapy**  Tiagabine is second-line therapy for patients with partial seizures who have failed initial therapy. It does not appear to have a role in primary generalized seizure types.

**Topiramate**

**Pharmacology and Mechanism of Action**  Topiramate is a sulfamate-substituted monosaccharide with multiple modes of action involving voltage-dependent sodium channels, GABA-receptor subunits, high-voltage calcium channels, and kainate/AMPA subunits. It also inhibits carbonic anhydrase, which likely is not a major mechanism of action.

**Pharmacokinetics**  Although generally considered to have linear absorption and elimination pharmacokinetics, a greater than...
Valproic acid appears to be absorbed completely from available oral dosage forms when administered on an empty stomach. However, the rate of absorption differs among preparations. Peak concentrations occur in 0.5 to 1 hour with the syrup, 1 to 3 hours with the capsule, and 2 to 6 hours with the enteric-coated tablet. The extended-release formulation (Depakote-ER) is FDA approved for patients with migraine headache and epilepsy. The bioavailability of this formulation is approximately 15% less than that of enteric-coated divalproex sodium (Depakote).

Valproic acid is extensively bound to albumin, and this binding is saturable. Accordingly, the valproic acid free fraction will increase as the total serum concentration increases. Because of this saturable binding, measurement of unbound serum concentrations may be a better monitoring parameter than the total valproic acid serum concentration, especially at higher concentrations or in patients with hypoalbuminemia.

The primary route of valproic acid metabolism is β-oxidation, although up to 40% of a dose may be excreted as the glucuronide. At least 10 metabolites of valproic acid have been identified. Some of these may have weak anticonvulsant activity, and at least one metabolite may be responsible for the hepatotoxicity reported. One of the lesser oxidative metabolites, 4-ene-VPA, causes hepatotoxicity in rats. The formation of this metabolite is increased when valproic acid is given with enzyme-inducing drugs. Valproic acid displays diurnal elimination with lower evening serum levels occurring than morning levels. It crosses into the placenta and concentrations may be up to 5 times higher in cord serum blood than in the mother due to higher binding in the fetal compartment.

Adverse Effects

The most frequently reported side effects are gastrointestinal (up to 20%), including nausea, vomiting, anorexia, and weight gain. Pancreatitis is rare. GI complaints may be minimized, but not totally alleviated, with the enteric-coated formulation or by giving the drug with food. Alopecia and hair changes are temporary, and hair growth returns even with continued dosing. Weight gain can be significant for many patients and is associated with an increase in fasting insulin and leptin serum levels. The increase in serum insulin is believed to be caused by the inhibition of metabolism of insulin by the liver. This has led to the development of insulin resistance in obese male and female subjects. Valproic acid causes minimal cognitive impairment.

The most serious side effect reported with valproic acid is hepatotoxicity. Hyperammonemia is common (50%) but does not necessarily imply liver damage. Most liver failure deaths have occurred in patients who were younger than 2 years of age, had mental retardation, and received multiple AEDs. Hepatotoxicity occurred early in the course of therapy. Patients who complain of nausea, vomiting, lethargy, anorexia, and edema in the first 6 to 12 months of therapy should have liver function evaluated. Multiple AEDs can alter the metabolism of valproic acid, leading to increased formation of the potentially liver-toxic 4-ene-VPA. Valproic acid has been shown to alter carnitine metabolism, and it has been postulated that a deficiency of carnitine alters fatty acid oxidation that could lead to both liver toxicity and hyperammonemia. However, valproic acid hepatotoxicity has occurred in a patient taking supplemental carnitine, and a prospective study demonstrated no effect on well-being when carnitine was added. Although carnitine can ameliorate hyperammonemia in part, it is expensive, and there are only limited data to support routine supplemental use in patients taking valproic acid.

Thrombocytopenia and alterations in platelet aggregation occur in the patients receiving valproic acid, and these phenomena are related to serum concentration. These blood coagulopathies may occur more frequently in children than in adults.

Valproic Acid/Divalproex Sodium

Pharmacology and Mechanism of Action

Alterations of the synthesis and degradation of GABA do not fully explain the antiseizure activity of valproic acid. Valproic acid may potentiate postsynaptic GABA responses, may have a direct membrane-stabilizing effect, and may affect potassium channels.
Drug Interactions Because it is highly protein bound, other highly protein-bound drugs (e.g., free fatty acids and aspirin) can displace valproic acid. Valproic acid can inhibit specific CYP P450 isozymes, epoxide hydrodase, and UGT isozymes. The addition of valproic acid to phenobarbital results in a 30% to 50% decrease in phenobarbital clearance and significant toxicity if the dose of phenobarbital is not reduced. Data also suggest that combination OCS may increase the clearance of valproic acid and lower serum levels by 20%.* In addition, carbamazepine, especially mephenytoin can lower valproic acid levels.\(^{134}\)

Dosing and Administration Valproic acid in some patients may have a half-life long enough for once-daily dosing with entericoated divalproex, but more frequent dosing is the norm. Based on half-life data, twice-daily dosing is feasible with any valproic acid dosage form; however, children and patients taking enzyme inducers can require dosing 3 to 4 times daily.\(^{73}\) The serum concentration—dose relationship is curvilinear (e.g., the concentration-dose ratio decreases with increasing dose) probably because of increasing free concentrations and a resulting increase in clearance.\(^{73}\)

Valproic acid is available as a soft gelatin capsule, an entericoated tablet, a syrup, a "sprinkle capsule," an extended-release formulation designed for once-daily dosing, and an IV formulation for replacement of oral therapy or in situations where rapid loading is necessary.\(^{127}\) This parenteral formulation must not be given intramuscularly because it can cause tissue necrosis. The sprinkle capsule, designed to be opened and mixed with food, has a slower rate of absorption, which results in fewer fluctuations in the peak-to-trough ratio. The syrup is absorbed more rapidly than any solid dosage form. The enteric-coated divalproex tablet is not sustained release. It must be metabolized in the gut to valproic acid. The enteric coating reduces GI distress. The enteric coating causes delayed absorption, although once the enteric coating dissolves, sodium divalproex has absorption, metabolism, and elimination rates similar to those of the gelatin capsule. If a patient is switched from Depakote to Depakote-ER, the dose should be increased by 14% to 20%. Depakote-ER may be given once daily.

Advantages Valproic acid is available in multiple dosage formulations. The IV formulation is especially well tolerated. It has a wide therapeutic index and is considered a broad-spectrum AED. It is also used in other neurologic or psychiatric disorders (e.g., migraine headache, bipolar disorder).

Disadvantages Some patients report significant weight gain with valproic acid, which may limit compliance. It has other side effects, such as alopecia, tremor, pancreatitis, PCOS, and thrombocytopenia. It has been associated with hepatic necrosis in young children. As an enzyme inhibitor, it is involved in multiple drug—drug interactions.

Place in Therapy Valproic acid is first-line therapy for primary generalized seizures, including myoclonic, atonic, and absence seizures. It can be used as both monotherapy and adjunctive therapy for partial seizures, and it can be very useful in patients with mixed seizure disorders.

Vigabatrin

Pharmacology and Mechanism of Action Vigabatrin is a racemic mixture consisting of two enantiomers with only the S(+)-enantiomer active. Vigabatrin is a selective, irreversible inhibitor of GABA-transaminase, the enzyme that degrades GABA, thereby increasing GABA levels in the CNS.\(^{135}\)

Pharmacokinetics Vigabatrin undergoes virtually no metabolism and is excreted unchanged in the urine.\(^{32}\) It is rapidly absorbed from the GI tract, and food has no effect on its absorption. Serum vigabatrin levels are linearly related to dosage, but therapeutic levels are not related to duration of effect; duration of effect is directly related to regeneration of the enzyme which metabolizes GABA. Since vigabatrin undergoes virtually no metabolism and is excreted renally, dosage adjustment is necessary in renally impaired patients. Children have a higher vigabatrin clearance than adults and therefore require higher mg/kg doses.\(^{32}\)

Adverse Effects Vigabatrin may aggravate seizures, particularly absence and myoclonic seizures in patients with generalized epilepsies. Patients with history of depression, psychosis, or behavioral disturbances may be at greater risk to develop psychiatric effects.\(^{133}\) Vigabatrin causes progressive, irreversible, bilateral concentric visual field constriction in a high percentage of patients. It may also reduce visual acuity in a dose-related and life exposure—related manner. Vigabatrin is associated with weight gain and edema, peripheral neuropathy, somnolence, and fatigue.\(^{32}\) In up to 11% of patients (up to age 3 years) treated with high doses of the drug for infantile spasms, magnetic resonance imaging (MRI) findings have been strongly suggestive of intramyelinic edema in select brain areas. These findings appear to be reversible, and their significance is unclear.\(^{156}\)

Drug Interactions Vigabatrin induces CYP2C and therefore decreases phenytoin plasma levels by approximately 20%. One study noted at least a 10% increase in serum carbamazepine levels in the majority of patients started on adjunctive therapy with vigabatrin, which has not been supported in clinical trials.\(^{35}\)

Dosing and Administration Vigabatrin’s initial dose in adults for refractory complex partial seizures is 1,000 mg/day given in two divided doses with an increase by 500 mg/day weekly until 3,000 mg/day is reached. Initial dose in infants and children for infantile spasms is 50 mg/kg/day given in two divided doses with an increase by 25 to 50 mg/kg/day every 3 days to maximum dose of 150 mg/kg/day.

Advantages Vigabatrin has been widely studied and used in numerous countries throughout the world.

Disadvantages Adverse effects are sizeable and significant. It is available only through a restricted distribution program (SHARE program), which requires providers and patients to register. Vision should be checked at baseline and every 3 months for up to 3 to 6 months after drug discontinuation.

Place in Therapy Vigabatrin is a first-line agent for infantile spasms, particularly those with tuberous sclerosis as the etiology. It is a third-line adjunctive agent for refractory partial epilepsy.

Zonisamide

Pharmacology and Mechanism of Action Zonisamide, a synthetic 1,2-benzisoxazole derivative classified as a sulfonamide, is chemically different from other AEDs. It is a broad-spectrum AED believed to exert its antiepileptic effect by inhibition of slow sodium channels, by blockade of T-type Ca²⁺ channels, and possibly by inhibition of glutamate release. It also has a weak carbonic anhydrase inhibitory effect.\(^{137}\)

Pharmacokinetics Zonisamide is well absorbed and reaches a maximum concentration in 2 to 5 hours. It is metabolized by CYP3A4 and to a much lesser extent by CYP2C19 and CYP3A5. Approximately 30% is excreted unchanged in the urine. Zonisamide is distributed to most tissues, but the drug is concentrated in the red blood cells. It crosses the placenta. The concentration in breast milk is similar to that in the plasma.\(^{137}\)

Adverse Effects The most common adverse effects of zonisamide include somnolence, dizziness, anorexia, headache, nausea, agitation, word-finding difficulties, and irritability. Adverse
effects may be more common during rapid dose escalation. Because it is structurally related to sulfonamides, hypersensitivity reactions can occur (0.02% of patients), and zonisamide should be used with caution (if at all) in patients with a confirmed allergy to sulfonamide compounds. A 2.6% incidence of symptomatic kidney stones has been reported in patients treated in the United States. 138 Because of reports of modest, reversible declines in renal function in some patients, monitoring of renal function may be advisable for certain patients. Oligohidrosis has been reported. In addition, modest weight loss has been reported with this agent. 24, 25, 75

**Drug Interactions** Zonisamide does not inhibit or induce the cytochrome P450 system.

**Dosing and Administration** Zonisamide is given once or twice daily, however, once-daily dosing causes greater fluctuations in serum concentrations and perhaps more side effects. The dose should be increased every 2 weeks to response. Zonisamide is stable for 48 hours when mixed with water, apple juice, or pudding.

**Advantages** Zonisamide has multiple mechanisms of action and may be a broad-spectrum AED. There is broad international experience with this drug. It has a very long half-life, which is suitable for once- or twice-daily dosing. Patients may experience modest weight loss.

**Disadvantages** The dose of zonisamide should be titrated slowly to patient response. Renal stones and oligohidrosis have been reported. In addition, cognitive impairment can occur, especially if the dosage is escalated rapidly. It should be avoided in patients allergic to “sulfa drugs.”

**Place in Therapy** Zonisamide is approved for the adjunctive treatment of partial seizures. Zonisamide is potentially effective in a variety of partial and primary generalized seizure types.

---

**PHARMACOECONOMIC CONSIDERATIONS**

**CLINICAL CONTROVERSY**

The place in therapy of the newer drugs is still being determined. The cost of the newer AEDs generally is much higher that that of the older drugs. Given that, in general, the efficacy of the newer drugs is comparable with that of the older agents, many clinicians (and patients) have been slow to adopt this newer generation of drugs. It is important to recognize that overall effectiveness encompasses both efficacy and tolerability assessments. Generally speaking, the newer generation of AEDs possess fewer adverse effects and seems to be better tolerated than older, far less expensive agents such as the barbiturates. Some may also have less costly long-term adverse effects such as effects on bone metabolism or the fetus, and they may cause fewer drug interactions, which require higher doses of drugs to avoid treatment failures. These differences may well justify the difference in cost, however, this needs to be determined on an individual basis.

The direct costs of epilepsy include the cost of the drug, treatment of adverse events, emergency room visits, drug levels, laboratory tests, physician visits, rehabilitation, and transportation. Indirect costs include the costs associated with time lost from work, the inability to get a job, decreased productivity, and mortality.

It is difficult to assess the cost of epilepsy to society. Pashko and coworkers, using a cohort of Pennsylvania Medicaid patients, estimated that the total direct cost of epilepsy is in excess of $10 billion annually, with the majority of the per-patient costs incurred for inpatient hospitalization (uncontrolled seizures or treatment-related toxicity). 139 Another study suggested that the direct costs of epilepsy made up approximately 37% of the total costs, with indirect costs accounting for the remainder. 140 This study also indicated that the costs were much less for a patient who is well controlled than for a patient who is poorly controlled. Drug costs in the Pashko study accounted for approximately 10% of the total costs of epilepsy. In a large retrospective trial involving Medicaid patients in Florida, New Jersey, and Iowa, it was determined that nonadherence in taking AEDs was associated with a significantly higher incidence of hospitalization and visits to the emergency room, which translated to a sizable increase in overall costs. 141 Providing the best QOL is possible is a treatment goal for patients with epilepsy, while maintaining a balance between side effects and the number of seizures. 142 QOL takes into account all the concerns of patients with epilepsy, including their social and economic concerns. This can best be assessed by the patient. Complete seizure freedom leads to the best QOL. In one study, driving was listed as the most important concern by 28% of patients, followed by employment (21%), independence (9%), safety (6%), AED side effects (5%), seizure unpredictability (5%), and seizure avoidance (5%). 143 Assessment of QOL as a therapeutic outcome ultimately may be more meaningful than measuring blood levels of the AEDs. It is clear that the cheapest drug in epilepsy (e.g., phenobarbital) is not the best because of the number of side effects. Drug therapy that controls seizures, decreases side effects, improves the QOL, and reduces the use of other healthcare resources would be cost-effective. Because epilepsy treatment continues to be highly individualized, the drug or combination of drugs that controls seizures with the least number of side effects will be the drug of choice for that patient no matter how expensive the drug acquisition cost.

Because many patients with epilepsy require minimal variation in blood concentrations to prevent seizures and avoid side effects, generic prescribing for epilepsy remains controversial. Issues related to generic use have been clearly delineated in the literature. 144, 145 A strong argument for the use of generic AEDs is that they will save huge amounts of money and should not cause harm, if patients are selected wisely, e.g., those who are newly diagnosed, or who are not fully controlled, or who are not seizure free on brand product. There is only one randomized study comparing brand name and generic drug products which involved Depakene versus generic valproic acid. This study found no difference between the products. However, substantial data continue to accumulate from large, retrospective, observational studies which indicate that generics may increase health care costs from emergency room visits and hospitalizations. In addition, utilization of multiple generics in the same patient may create problems. A recent retrospective trial studied patients being treated with multiple topiramate generics and reported an increase in hospitalizations and injuries, again supporting increased health care costs with use of generics. 146 What has yet to be determined is whether bioequivalence translates into therapeutic equivalence in the use of generic AEDs and whether there is a subset of patients where this is not true.

**EVALUATION OF THERAPEUTIC OUTCOMES**

A therapeutic range should be established for each patient to define concentrations that result in minimal side effects and optimal seizure control. This therapeutic plasma concentration range should
be used to identify the appropriate patient-specific dose. Patients should be monitored long term for seizure control, comorbid conditions, social adjustment (including QOL assessments), drug interactions, compliance, and adverse effects. Periodic screening for comorbid neuropsychiatric disorders such as depression and anxiety is also important. Clinical response is more important than the serum drug concentrations.

Outcomes can be assessed by regular clinical monitoring, drug utilization review, and QOL assessments. Clinical monitoring involves identifying the number and type of seizures. Patients should record the severity and the frequency of seizures in a seizure diary. There should be a decrease in the number and/or severity of seizures. Patients and family should be questioned regularly to determine whether they are truly seizure free.

The treatment of epilepsy begins with a careful identification of the seizure type and selection of the most appropriate AED. Therapy should be initiated slowly, except in life-threatening situations, to avoid acute toxicity. Although most patients can be managed successfully on monotherapy, some patients’ seizures remain uncontrolled despite the use of multiple AEDs. Some patients may be genetically refractory to AED therapy. The newer AEDs, as adjunctive therapy or monotherapy, offer additional opportunity to achieve complete seizure control. There is a continuing need for new AEDs and additional research in this area.

**ABBREVIATIONS**

AAN: American Academy of Neurology
AED: antiepileptic drug
AES: American Epilepsy Society
AMPA: α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid
CNS: central nervous system

Neurologic Disorders

Status Epilepticus

KEY CONCEPTS

1. Status epilepticus (SE) is a neurologic emergency that is associated with significant morbidity and mortality.
2. Generalized convulsive status epilepticus (GCSE) is defined as any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. Any seizure that does not stop within 5 minutes should be treated as impending SE.
3. There are two types of status epilepticus, GCSE and nonconvulsive status epilepticus (NCSE). GCSE is the most common type.
4. Most GCSE develops in patients with no history of epilepsy; however, a patient with preexisting epilepsy may experience GCSE as a result of acute anticonvulsant withdrawal, metabolic disorder, concurrent illness, or progression of neurologic disease.
5. Although the pathophysiology of GCSE is unknown, experimental models have shown that there is a dramatic decrease in γ-aminobutyric acid–mediated inhibitory synaptic transmission and that glutamatergic excitatory synaptic transmission sustains the seizures.
6. General treatment includes patient stabilization, adequate oxygenation, preservation of cardiorespiratory function, management of systemic complications, and aggressive assessment of underlying causes.
7. The main purpose of treatment is to prevent or decrease morbidity and mortality of prolonged seizures. Pharmacologic treatment needs to be rapid and aimed at terminating both electrical and clinical seizures. The probability of poorer outcomes increases with increased length of electrographic seizure activity.
8. Lorazepam is the preferred benzodiazepine in treatment of GCSE because of its long duration of action in the CNS.
9. Currently, the hydantoinos (phenytoin and fosphenytoin) are the long-acting anticonvulsants used most frequently. Either phenytoin or fosphenytoin should be given concurrently with benzodiazepines.

The maximum rate of infusion for phenytoin and fosphenytoin in adults is 50 mg/min and 150 mg PE/min, respectively.

If GCSE is not controlled by two first-line agents (benzodiazepine plus hydantoin or phenobarbital), the GCSE is considered to be refractory. In these cases, newer anticonvulsants and/or pharmacologically induced coma should be used.

Status epilepticus (SE) is a neurologic emergency that is associated with brain damage and death. The traditional definition, provided by the International League Against Epilepsy Classification of Epileptic Seizures, defines SE as (1) any seizure lasting longer than 30 minutes whether or not consciousness is impaired or (2) recurrent seizures without an intervening period of consciousness between seizures. Clinically, this definition has limited use, particularly in the case of generalized convulsive status epilepticus (GCSE), as the average seizure is less than 2 minutes; and only 40% of seizures lasting 10 to 29 minutes cease without treatment. Pharmacoresistance and mortality significantly increase with increased seizure duration. Therefore, aggressive treatment of seizures lasting 5 minutes or more is strongly recommended. SE can present in several forms (Table 66–1), including GCSE and nonconvulsive status epilepticus (NCSE).

NCSE occurs in approximately 25% of those with SE and is characterized by a fluctuating or continuous “twilight” state that produces altered consciousness and/or behavior (e.g., lethargy, decreased mental function). An altered electroencephalogram (EEG) is the most important diagnostic and management tool. In most instances, a benzodiazepine and/or valproate remain drugs of choice for NCSE. Although intravenous (IV) hydantoin or phenobarbital can be tried in patients who fail to respond, general anesthesia or barbiturate coma is not appropriate. The reader is referred to a recent review for a more comprehensive discussion of NCSE and its pharmacologic management.

GCSE is the most common and severe form of SE and is characterized by repeated primary or secondary generalized seizures that involve both hemispheres of the brain and are associated with a persistent postictal state. This chapter will focus on the epidemiology, pathophysiology, presentation, and management of GCSE.

EPIDEMIOLOGY

It is difficult to determine the true incidence of GCSE. The worldwide and United States incidence is thought to range between 1.2 to 5 million and 100,000 to 152,000 cases each year, respectively. GCSE has no predilection for gender or socioeconomic status but does occur more frequently in nonwhites across all ages. Most episodes of GCSE occur in individuals with no history of epilepsy;
however, approximately 5% of adults and 10% to 25% of children with epilepsy will develop GCSE. The incidence of GCSE is highest in those younger than 1 year of age and in those older than 60 years of age.

**ETIOLOGY**

Precipitating events for GCSE vary among studies and generally reflect different populations and referral patterns. Most episodes that occur in known epileptics occur because of acute anticonvulsant withdrawal, a metabolic disorder or concurrent illness, or progression of a preexisting neurologic disease. Common etiologies and mortality rates are shown in Table 66–2. Precipitating events for GCSE are divided into those with and without neurologic structural lesions or those with a precipitating injury or insult. Cases with structural lesions or those with a specific neurologic insult are associated with a poor prognosis.

There are major differences in etiologies for pediatric and adult patients (see Table 66–2). During their first few weeks of life, infants who are born to addicted mothers can develop drug withdrawal seizures. Other neonates can develop GCSE because of a pyridoxine deficiency, which should resolve within hours following IV pyridoxine (100 mg). Acute encephalopathy and metabolic disorders are the major causes of GCSE in patients younger than 1 year of age. In young children, the cause is frequently a nonspecific illness such as fever and/or a viral illness. The most frequent precipitating events in adults are cerebrovascular disease, anticonvulsant withdrawal, and low anticonvulsant serum concentrations. Cerebrovascular disease is the leading cause in those who have their first seizures after age 60. A number of prescription, over-the-counter, and recreational drugs should be considered in anyone with new-onset GCSE. Elevated anticonvulsant serum concentration or rapid anticonvulsant withdrawal can also precipitate GCSE.

**MORBIDITY AND MORTALITY**

GCSE is harmful to the brain and is associated with morbidity. However, whether the morbidity results from the underlying etiology or the GCSE itself remains to be determined. Most contend that the GCSE is responsible for the morbidity. Neuronal damage in animal models is evident following 30 to 60 minutes of GCSE regardless of the inducing stimulus, and most animals progress to develop epilepsy following a prolonged seizure. Interestingly, inhibiting the neuronal damage associated with seizures does not prevent the development of epilepsy, suggesting that the seizures themselves may be harmful. It is hard to establish a relationship between GCSE and long-term outcomes because it is difficult to weigh the effects of seizure type, etiology, duration, concurrent physiologic events, and therapy or lack thereof. It has been shown that patients with a history of prolonged febrile seizures who later developed epilepsy share similar histopathologic changes (i.e., hippocampal sclerosis) to those found in animal models of GCSE.

In these cases the period between the initial GCSE and the first epileptic seizure may be months to decades, suggesting a possible link between GCSE and the development of epilepsy. Importantly, studies of GCSE show that the currently available anticonvulsants do not reproducibly prevent the development of epilepsy following prolonged seizures.

Patients who develop epilepsy following prolonged GCSE are less likely to experience remission of their seizures and may have decreased cognitive and memory function, mental retardation, or neurologic deficits. Most studies have found that younger children, the elderly, and those with preexisting epilepsy have a higher propensity for sequelae. Unless accompanied by an underlying neurologic abnormality, fever-induced GCSE is less likely to be associated with sequelae.

The estimated mortality rate in the United States following GCSE ranges between 22,000 and 42,000 individuals per year. Recent
estimates suggest a mortality rate of up to 16% in children,12 20% in adults,4 and 38% in the elderly.5 When compared with other populations, neonates have a higher mortality and more neurologic sequelae.

Table 66–2 summarizes the etiology and corresponding mortality rates for GCSE.6,8 Interestingly, the mortality associated with many etiologies is significantly greater in adults than in children. Unresponsive patients may die from GCSE, but more frequently they die from the acute illness that precipitated the GCSE. For example, patients with serious central nervous system (CNS) structural changes (e.g., hemorrhage, stroke) have a poor prognosis, whereas those (i.e., 80%–90%) with no structural lesion generally respond to IV phenytoin.

Two variables that affect outcome are the time between onset of GCSE and the initiation of treatment and the duration of the seizure. Mortality significantly increases with increased seizure duration (e.g., 2.6% for those with seizures 10–29 minutes vs 19% for those with seizures lasting >30 minutes).2 Patients with GCSE lasting longer than 60 minutes have a higher mortality rate (32%) than those with seizures lasting less than 60 minutes (2.5%).9 Mortality has decreased over the past decade and probably reflects a recognition of the need to initiate sequenced therapy immediately, and a greater understanding of the pathogenesis of GCSE.

PATHOPHYSIOLOGY

As GCSE continues, there are systemic alterations, progression of motor phenomena, and development of specific EEG findings.11 Two distinct and predictable phases have been identified. Phase I occurs during the first 30 minutes of seizure activity, and phase II immediately follows. Although these systemic complications affect the prognosis of GCSE, a prolonged seizure can destroy neurons independent of these systemic events. In fact, the systemic effects of induced seizures in animals can be blocked, but the damage to the neocortex, cerebellum, and hippocampus persists.

During phase I, each seizure produces marked increases in plasma epinephrine, norepinephrine, and steroid concentrations that can cause hypertension, tachycardia, and cardiac arrhythmias.13 Within minutes, arterial systolic pressures can rise to above 200 mm Hg, and heart rate can increase by 83 beats per minute. Although blood pressure returns to normal within 60 minutes, mean arterial pressure does not fall below 60 mm Hg; hence, cerebral perfusion pressure is not compromised. In animals, cerebral blood flow is also increased, thereby protecting neurons from hypoxic injury.

Seizure-induced increases in sympathetic and parasympathetic stimulation of the heart, in the presence of a hypoxic myocardium, can result in ventricular arrhythmias. Autonomic neuron stimulation can cause a release of insulin and glucagon. Concurrently, circulating catecholamines cause an elevation of hepatic cyclic adenosine monophosphate, producing glycolysis. Although the patient can be hyperglycemic initially, serum glucose concentration begins to fall.

Seizure-induced muscular contractions and hypoxia cause lactic acid release, which can produce a severe acidosis that can be accompanied by hypotension and shock. Muscle contractions can be so severe that rhabdomyolysis with secondary hyperkalemia and acute tubular necrosis can occur. The airway can be obstructed, causing the patient to become cyanotic or hypoxic. Additionally, an increase in salivation and tracheal and pulmonary secretions can cause aspiration pneumonia. Although transient pleocytosis can develop, it should not be attributed to SE until infectious causes have been eliminated.

Between seizures, the EEG slows, and blood pressure normalizes. Although metabolic demands are increased, the brain is able to adequately compensate. During phase II (e.g., seizures exceed 30 minutes), the EEG ictal discharge and clonic motor activity become continuous, and the patient begins to decompensate. Despite elevated levels of catecholamines, the patient can become hypotensive. During this time, autoregulation of cerebral blood flow becomes dependent on mean arterial pressure and begins to fail. There continues to be an excessive consumption of oxygen and glucose; however, compensatory mechanisms are no longer able to keep up with demands.

During this time, the serum glucose concentration may be normal or decreased. Profound hypoglycemia, secondary to hyperinsulinemia, can occur in those with hepatic dysfunction or reduced glycogen stores. Hyperthermia and respiratory deterioration with hypoxia and ventilatory failure can develop. Metabolic and
biochemical complications, including respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and azotemia may develop. There is increased sweating and salivation.

### CLINICAL PRESENTATION OF GCSE

#### Symptoms
- Impaired consciousness (e.g., lethargy to coma)
- Disorientation once GCSE is controlled
- Pain associated with injuries (e.g., tongue lacerations, shoulder dislocations, head trauma)

#### Early Signs
- Generalized convulsions
- Acute injuries or CNS insults that cause extensor or flexor posturing
- Hypothermia or fever suggestive of intercurrent illnesses (e.g., sepsis or meningitis)
- Incontinence
- Normal blood pressure or hypotension and respiratory compromise

#### Late Signs
- Clinical seizures may or may not be apparent
- Pulmonary edema with respiratory failure
- Cardiac failure (dysrhythmias, arrest, cardiogenic shock)
- Hypotension or hypertension
- Disseminated intravascular coagulation, multisystem organ failure
- Rhabdomyolysis
- Hyperpyremia

#### Initial Laboratory Tests
- Complete blood count (CBC) with differential
- Serum chemistry profile (e.g., electrolytes, calcium, magnesium, glucose, serum creatinine, alanine aminotransferase [ALT], aspartate aminotransferase [AST])
- Urine drug/alcohol screen
- Blood cultures
- Arterial blood gas to assess for metabolic and respiratory acidosis
- Serum drug concentration if previous anticonvulsant suspected or known

#### Other Diagnostic Tests
- Spinal tap if CNS infection suspected
- EEG should be obtained on presentation and once clinical seizures are controlled
- CT with and without contrast
- MRI
- Radiograph if indicated to diagnose fractures

### CLINICAL PRESENTATION AND DIAGNOSIS

Accurate diagnosis requires observation, physical examination, laboratory assessment, EEG, and neurologic imaging. The nature and duration of the seizure should be obtained, and a diagnosis of GCSE should not be made until a clinician has observed at least one seizure. Most patients have an altered consciousness that ranges from obtunded to marked lethargy and somnolence with pronounced eye-open unresponsiveness and waxy rigidity. Motor features can include muscle contractions, extensor or flexor posturing, and spasms. Over time, the clinical manifestations become less apparent. This has important ramifications in that seizures appear to have terminated without treatment or when an ineffective therapy is given.

In addition to an assessment of language and cognitive abilities, the physical and neurological examinations should assess motor, sensory, and reflex abnormalities, pupillary response, asymmetry, and posturing. The patient should also be examined for secondary injuries (e.g., tongue lacerations, shoulder dislocations, and head and facial trauma).

Laboratory tests are essential to the diagnosis of various etiologies. Hypoglycemia, hyponatremia, hypernatremia, hypomagnesemia, hypocalcemia, and renal failure can all cause seizures. A urine drug screen can help eliminate the possibility of illicit drug use or drug overdose. Serum drug concentration(s) should be obtained in those on chronic anticonvulsants, because high concentrations of certain medications can induce seizures, and low concentrations can reflect noncompliance or rapid drug withdrawal. A baseline serum concentration is necessary to determine whether a loading dose of a specific anticonvulsant is required. Assessment of other laboratory parameters (e.g., albumin, renal function, and hepatic function) that affect anticonvulsant dosing also can be useful. An EEG is a valuable diagnostic tool, particularly in those with prolonged GCSE in whom clinically apparent seizures are not always evident, but therapy should not be delayed while awaiting testing or results.

Once seizures have stopped, it is important to determine if the patient is febrile or has a systemic or CNS infection. Many physiologic consequences of GCSE (e.g., leukocytosis, pleocytosis, and hyperthermia) produce symptoms that can be confused with other conditions. If a CNS infection is suspected, empiric antibiotics should be started, and a spinal tap should be performed. Computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained to eliminate vascular, neoplastic, or infectious etiologies.

### TREATMENT

Various treatments are available for the management of GCSE. These range from abortion of impending SE with rescue medications to the use of pharmacological and nonpharmacological therapies for GCSE and refractory/resistant SE.

#### DESIRED OUTCOMES

The short-term desired outcomes of treatment of GCSE are (1) immediate termination of all clinical and electrical seizure activity, (2) no clinically significant adverse effects, and (3) lack of recurrent seizure activity. The long-term desired outcomes are to minimize or avoid the likelihood of pharmacoresistant epilepsy and/or the development of neurologic sequelae that significantly impact quality of life.

#### NONPHARMACOLOGIC THERAPY

Vital signs should be assessed, an adequate and protected airway should be established, ventilation should be maintained, and oxygen should be administered. Frequent arterial blood gas determinations should assess for metabolic acidosis, which should be treated with sodium bicarbonate if the pH is less than 7.2. Assisted ventilation should be used to correct respiratory acidosis.
PREHOSPITAL CARE

- Monitor vital signs (HR, RR)
- Consider PR diazepam (0.5 mg/kg/dose up to 10–20 mg) or IM midazolam (0.1–0.2 mg/kg)
- Transport to hospital if seizures persist

INITIAL HOSPITAL CARE

- Assess and control airway and cardiac function; pulse oximetry
- 100% oxygen
- Place IV catheter
- Intraosseous if unable to place IV and patient is older than 6 y
- Begin IV fluids
- Thiamine 100 mg (adult)
- Pyridoxine 50–100 mg (infant)
- Glucose (adult: 50 mL of 50%; children: 1 mL/kg of 25%)
- Naloxone 0.1 mg/kg for suspected narcotic overdose
- Antibiotics if suspected infection

LABORATORY STUDIES

- CBC with differential
- Serum chemistry profile (e.g., electrolytes, glucose, renal/hepatic function, calcium, magnesium)
- Arterial blood gas
- Blood cultures
- Serum anticonvulsant concentration
- Urine drug/alcohol screen

EARLY STATUS

0–10 min
- IV lorazepam (4 mg adults; 0.03–0.1 mg/kg at 2 mg/min pediatrics) may repeat if no response in 5 min
- Additional therapy may not be required if seizures stop and cause identified

10–30 min
- IV phenytoin or fosphenytoin PE
  - a adults: 10–20 mg/kg at rate of 50 mg/min or 150 mg/min PE, respectively; infants/children: 15–20 mg/kg at a rate of 1–3 mg/kg/min

ESTABLISHED STATUS (30–60 min)

Seizures continue:
- Additional IV 5 mg/kg dose of either phenytoin or fosphenytoin PE may be given in unresponsive patients
- IV phenobarbital 20 mg/kg at a rate of 100 mg/min in adults and 30 mg/min in infants/children

REFRACTORY STATUS (>60 min)

Clinical or electrical seizures continue:
- IV phenobarbital additional 10 mg/kg; 10 mg/kg may be given every hour until seizures stop or
- IV valproate 15–25 mg/kg followed by 1–4 mg/kg/h
- General anesthesia with either
  - IV midazolam 2 mg/kg bolus followed by 50–500 mcg/kg/h
  - IV pentobarbital 15–20 mg/kg bolus over 1 h then 1–3 mg/kg/h to burst suppression on EEG. If hypotension occurs slow rate of infusion or begin dopamine or
  - IV propofol 1–2 mg/kg bolus followed by ≤4 mg/kg/h

Once seizures controlled, taper midazolam, pentobarbital, propofol over 12 hours. If seizures recur start infusion and titrate to effective dose over 12 hours.

FIGURE 66–1. Algorithm for the treatment of GCSE. (CBC, complete blood count; EEG, electroencephalogram; GCSE, generalized convulsive status epilepticus; HR, heart rate; PR, per rectum; RR, respiratory rate.) *Because variability exists in dosing, monitor serum concentration. †If seizure is controlled, begin maintenance does and optimize using serum concentration monitoring.

Because electrical seizures may persist in the absence of clinical motor manifestations, an EEG should be performed in anyone who continues to have altered consciousness after clinical control of their seizures. Although hypoglycemia rarely causes GCSE, adults and children should receive 50 mL of a 50% dextrose solution, and 1 mL/kg of a 25% dextrose solution, respectively. Because Wernicke encephalopathy can develop in alcoholics, adults should receive IV thiamine (100 mg) prior to glucose. Serum glucose concentration should be determined to assess the need for further supplementation.

PHARMACOLOGIC THERAPY

When a seizure does not stop within 5 minutes, or when doubt exists regarding the diagnosis, patients should be treated as if they have GCSE. Figure 66–1 provides an algorithm for the treatment of GCSE.
There are four immediate goals in the management of GCSE: (1) patient stabilization, including adequate oxygenation, preservation of cardiorespiratory function, and management of systemic complications; (2) accurate diagnosis of the subtype of GCSE and identification of precipitating factors; (3) termination of clinical and electrical seizures as early as possible; and (4) prevention of seizure recurrence. The benzodiazepines, hydantoins, and barbiturates are the most commonly used classes of anticonvulsants for the initial treatment of GCSE.

### Benzodiazepines

The benzodiazepines are effective initial therapy in most patients and should be administered as soon as possible. Generally, one or two IV doses will terminate seizures within 2 to 3 minutes.\(^4\) All benzodiazepines are equally effective; therefore, the preferred agent is determined by differences in the pharmacokinetic, pharmacoeconomic, and adverse-effect profiles.

Diazepam is extremely lipophilic with a large volume of distribution (1–2 L/kg).\(^15\) Although it initially distributes into the brain within seconds, it rapidly redistributes into fat, causing its CNS half-life to be less than 1 hour and its duration of effect to be less than 30 minutes.\(^15\) The rapid decrease in brain concentration can cause seizure recurrence; hence, a longer-acting anticonvulsant (e.g., phenytoin or phenobarbital) should also be given. The initial dose of diazepam (Table 66–3) can be repeated if there is no response within 5 minutes.\(^16\)

Most practitioners consider lorazepam the benzodiazepine of choice.\(^4,15\) A recent Cochrane Database Review concluded that lorazepam is as effective and safer than diazepam in children.\(^4\) It is less lipid soluble than diazepam and takes longer to achieve peak concentrations in the brain; however, its minimal redistribution into fat results in a longer duration of action in the CNS that can provide seizure protection for up to 24 hours.\(^4,15\) It also has a higher-affinity binding to the benzodiazepine receptor than diazepam.

Initial lorazepam dosing (Table 66–3) can be repeated if the patient does not respond in 5 minutes.\(^4,15\) Patients chronically on a benzodiazepine (e.g., clonazepam) might have developed tolerance and could require larger doses than other patients. Diazepam and lorazepam cause vein irritation and should be diluted with an equal volume of compatible diluent before administration. Diazepam and lorazepam contain propylene glycol, which can cause dysrhythmia and hypotension if administered too rapidly.\(^15\) Because of slow and erratic absorption, they should not be given intramuscularly (IM).

---

### CLINICAL CONTROVERSY

The positioning of midazolam among the medications used to treat GCSE is controversial. Some investigators recommend that midazolam should be the anticonvulsant of first choice and, therefore, should be used in lieu of lorazepam; others argue that it should be used after a hydantoin has failed; still others recommend it only for refractory GCSE.

Unfortunately, midazolam has an extremely short half-life and must be given by continuous infusion. Various routes of administration (e.g., buccal, IM, intranasal) have been used successfully to terminate seizures when IV access cannot be established. Because of its increased solubility, midazolam has a more reliable IM absorption than either diazepam or lorazepam. In fact, some practitioners have recommended that IM midazolam be given by emergency personnel as first-line treatment in the out-of-hospital setting.\(^17\) Buccal administration is easily accomplished, the volume of fluid is small enough (e.g., 2–5 mL) that aspiration is unlikely. A recent Cochrane Database Review concluded that buccal midazolam is more effective than rectal diazepam in children.\(^18\)

All benzodiazepines can impair consciousness and interfere with neurologic assessment. Although rare, brief (less than 1 minute) cardiorespiratory depression can necessitate assisted ventilation or require intubation. This is especially true if a benzodiazepine is used concomitantly with a barbiturate. Hypotension secondary to a reduction in vasomotor tone can occur following large doses.\(^4\)
Phenytoin

A hydantoin is the second-line agent in GCSE that is unresponsive to the benzodiazepines or in seizures that recur after successful treatment with a benzodiazepine. Although it is effective in terminating seizures in 40% to 91% of patients, it can be inferior to lorazepam, phenobarbital, or diazepam plus phenytoin at stopping GCSE within 20 minutes of their infusion.

Phenytoin has a long half-life (20–36 hours) and causes less respiratory depression and sedation than the benzodiazepines or phenobarbital, however, it cannot be delivered rapidly enough to be considered a first-line single agent. Injectable phenytoin should be diluted to less than or equal to 5 mg/mL in normal saline. Microcrystals will precipitate if it is mixed in a glucose-containing solution. The vehicle (40% propylene glycol) can cause administration-related hypotension and cardiac arrhythmias. These effects are more likely to occur if large loading doses are given to elderly individuals with preexisting cardiac disease or in critically ill patients with marginal blood pressure. Vital signs and an ECG should be obtained during administration. The infusion rate should be slowed if the QT interval widens or if hypotension or arrhythmias develop. The maximum rate of infusion is 50 mg/min in adults, 25 mg/min in the elderly, and 3 mg/kg/min in children weighing less than 50 kg (110 lb).

Suggested IV loading doses are provided in Table 66–3. A reduction in the loading dose is recommended for elderly patients, and a larger loading dose is required in obese individuals. If the patient has been on phenytoin prior to admission and the serum concentration is known, this should be considered in determining a loading dose. Although some advocate the administration of an additional 5 mg/kg in those with unresponsive GCSE, there is no evidence that this will be beneficial. This practice can cause concentrations to exceed the reference range and produce toxicity. Because phenytoin has poor lipid solubility and enters the brain slowly, it can take up to 60 minutes before the pharmacodynamic effect is apparent. This delay is important when considering administration of a second 5 mg/kg loading dose. Therapeutic serum concentrations, 10 to 20 mg/L (40–79 μmol/L), generally do not persist more than 24 hours; hence, maintenance doses (see Table 66–3) should be started within 12 to 24 hours of the loading dose.

Phenytoin has an alkaline pH, which may cause pain and burning during infusion; phlebitis can occur with chronic infusion, and tissue necrosis is likely on infiltration. IM administration is not recommended because absorption is delayed and erratic, and phenytoin can crystallize in tissue. Although oral loading doses have been used in patients not actively seizing, it may take 4 to 12 hours before adequate serum concentrations are obtained; thus, this practice is not recommended.

There are three different opinions regarding the use of phenobarbital in GCSE. Because barbiturates cause CNS and respiratory depression, as well as hypotension, most contend that phenobarbital should be the third-line agent when a benzodiazepine plus phenytoin has failed. Others suggest that the barbiturates are as safe and effective as other anticonvulsants and should be the drug of choice following a benzodiazepine. Still others support continuous-infusion midazolam as the third-line anticonvulsant before the barbiturates. Currently, most practitioners agree that phenobarbital is the long-acting anticonvulsant of choice in patients with hypersensitivity to the hydantoins or in those with cardiac conduction abnormalities.

Phenobarbital

Phenobarbital has biphasic distribution into body organs. During phase I, the drug distributes into highly vascular organs, but it does not distribute into the brain. With the exception of fat, phenobarbital distributes throughout the body during phase II; hence, lean body mass should be used in calculating doses in obese patients.

Although the highest brain concentrations occur 12 to 60 minutes after an IV dose, seizures are controlled within minutes of the loading dose. Despite two studies that found phenobarbital to be as effective as phenytoin, lorazepam, or diazepam plus phenytoin in patients with GCSE, the Working Group on Status Epilepticus recommends that phenobarbital be given after a benzodiazepine plus phenytoin has failed.

The loading and maintenance dose are given in Table 66–3. When necessary, larger loading doses (30 mg/kg) have been used in neonates without adverse effects. If the initial loading dose does not stop the seizures within 20 to 30 minutes, an additional 10 to 20 mg/kg can be given. If seizures continue, a third 10 mg/kg load can completely (100%) to phenytoin by blood and tissue phosphatases after IV and IM dosing. The conversion delay was a concern initially; however, this time is offset by high protein binding, saturable binding at high concentrations, and the rapid rate of infusion. It does not contain propylene glycol and is compatible with most common IV fluids.

Nystagmus, dizziness, and ataxia are the most frequent adverse events and are attributed to phenytoin. The frequency of ECG or blood pressure changes is less than that for phenytoin. Nonallergic paresthesias and pruritis of the face and groin are unique to fosphenytoin and are related to dose and infusion rate, and rarely require discontinuation of fosphenytoin. These side effects typically subside within 5 to 10 minutes after the infusion.

Fosphenytoin should be dosed using phenytoin equivalents (PE), thereby obviating the need for interchange between phenytoin and fosphenytoin. The loading dose and rates of administration of fosphenytoin can be found in Table 66–3. Because of delays in achieving adequate phenytoin serum concentrations, a loading dose should not be given IM unless IV access is impossible. Continuous ECG, blood pressure, and respiratory status monitoring is recommended for all loading doses.

Fosphenytoin serum concentrations have no value. Serum phenytoin concentrations should be used for therapeutic drug monitoring, and the desired serum concentration range is the same as that for phenytoin. Fosphenytoin cross-reacts with some phenytoin immunoassays causing an overestimation of phenytoin concentration; hence, blood should not be obtained for at least 2 hours after IV and 4 hours after IM administration.

---

**Clinical Controversy**

The debate continues as to which hydantoin is preferred in GCSE. Although phenytoin has been used for decades, it is associated with a variety of problems related to its formulation. Conversely, fosphenytoin is associated with less infusion pain and IV-site complications and fewer hemodynamic effects than phenytoin. Although most practitioners believe that fosphenytoin is clearly a “better” formulation, many struggle with the advantages of fosphenytoin, given its cost.

**Fosphenytoin**

Fosphenytoin, a water-soluble phosphate ester, has no known pharmacologic activity. It is converted rapidly (7–15 minutes) and completely (100%) to phenytoin by blood and tissue phosphatases after IV and IM dosing. The conversion delay was a concern initially; however, this time is offset by high protein binding, saturable binding at high concentrations, and the rapid rate of infusion. It does not contain propylene glycol and is compatible with most common IV fluids.
be given. Phenobarbital exhibits first-order linear pharmacokinetics, and there is no maximum dose beyond which further doses are likely to be ineffective. Once GCSE is controlled, the maintenance dose should be started within 12 to 24 hours.

Although injectable phenobarbital contains propylene glycol, it can be given more rapidly than phenytoin (see Table 66–3). It can be given IM, but its rate of absorption is too slow to be effective. Phenobarbital can depress consciousness and respiration. The risk of apnea and hypopnea can be more profound in patients treated initially with benzodiazepines. If significant hypotension develops, the infusion should be slowed or stopped.

TREATMENT OF REFRACTORY GCSE

When adequate doses of a benzodiazepine, hydantoin, or barbiturate have failed, the condition is termed refractory. Approximately 10% to 15% of patients will develop refractory GCSE, and approximately 30% whose seizures are “clinically” controlled will have persistent electrical manifestations after administration of these anticonvulsants. When a patient develops refractory GCSE, an intense search should be performed for an acute or progressive cause.

It should be remembered that the longer GCSE lasts, the harder it is to treat and that failure to treat aggressively early in the course of disease increases the likelihood of nonresponse. While the goal is to treat and that failure to treat aggressively early in the course of disease increases the likelihood of nonresponse. While the goal is to stop electrical epileptiform activity, there is no consensus regarding the anticonvulsant of choice, sequencing of therapy, or treatment of refractory GCSE. Approaches used include the continuous infusion of a benzodiazepines, medically induced coma, valproate, lacosamide, levetiracetam, topiramate, propofol, or lidocaine. Doses for these agents can be found in Table 66–4. A meta-analysis compared midazolam, propofol, and pentobarbital in refractory GCSE. Overall response rates were significantly greater in those treated with pentobarbital (92%) compared to midazolam (80%) and propofol (73%). Breakthrough seizures were more commonly observed with midazolam (51%) versus propofol (15%) and pentobarbital (12%). Although pentobarbital had a greater response rate, clinically significant hypotension was more common. Mortality rates were similar for the three drugs.

Benzodiazepines

Some advocated that anesthetic doses of midazolam should be the first-line agent in refractory GCSE. Table 66–4 contains the loading and maintenance doses of midazolam. Most patients respond to these doses within an hour, but the continuous-infusion rate should be increased every 15 minutes in those who do not. Because tachyphylaxis can develop, frequent increases in the infusion rate can be necessary, and dosing should be guided by EEG response.

Once GCSE is terminated, dosages can be decreased by 1 mcg/kg every 2 hours. Successful discontinuation is enhanced by maintaining the patient’s phenytoin and phenobarbital serum concentration(s) above 20 mg/L (79 μmol/L) and 40 mg/L (172 μmol/L), respectively. Because of midazolam’s short half-life, patients can return to consciousness more rapidly than those receiving larger doses of more sedating anticonvulsants (e.g., phenytoin, phenobarbital). Generally, continuous-infusion midazolam has been well tolerated, with few cases of hypotension and respiratory depression. Hypotension and poikilothermia can occur and can require supportive therapies.

Large-dose continuous-infusion lorazepam also has been used successfully. Unlike midazolam, lorazepam contains propylene glycol, which can accumulate during continuous infusions. Propylene glycol toxicity can cause a marked osmolar gap, metabolic acidosis, and renal toxicity.

**Medically Induced Coma**

If there is an inadequate response to large doses of midazolam, anesthetizing the patient to suppress the cerebral ictal discharge is recommended. Although it is likely that the patient is already being mechanically ventilated, intubation and respiratory support are mandatory during barbiturate coma. Because hypotension is a concern, it is essential that vital signs be monitored continuously. A short-acting barbiturate (usually either pentobarbital or thiopental) generally is preferred because it allows a more rapid reversal of coma.

Several sources note that the initial loading dose of pentobarbital is 5 mg/kg. However, this dose is inadequate to achieve the serum concentrations (40 mg/L; 177 μmol/L) necessary to induce an isoelectric EEG. Pentobarbital should be initiated with a loading dose of at least 10 to 20 mg/kg over 1 to 2 hours (see Table 66–4). If hypotension occurs during the loading dose, the rate of administration should be slowed, or dopamine should be administered. The loading dose should be followed immediately by a continuous infusion. Rates are typically begun at 1 mg/kg/h and titrated as needed up to a dose of 5 mg/kg/h. The maintenance infusion should be increased gradually until there is evidence of burst suppression on EEG (i.e., isoelectric EEG) or prohibitive adverse effects occur. Although the duration of barbiturate coma in most studies has been 2 to 3 days, it has been used safely for 53 days in

GCSE, generalized convulsive status epilepticus; NA, not available; PO, orally.

Doses can be repeated twice every 10 to 15 minutes until the maximum dosage is given.

Titrate dose as needed.

Generally recommended not to exceed a dose of 4 mg/kg/h and a duration of 48 hours.
an 18-year-old patient.\textsuperscript{29} To avoid complications (e.g., pneumonia, pulmonary edema), the pentobarbital should be discontinued as soon as possible. Twelve hours after a burst-suppression pattern is obtained, the rate of pentobarbital infusion should be titrated downward every 2 to 4 hours to enable the clinician to determine if the patient’s GCSE is in remission. It is important to have other anticonvulsants at therapeutic amounts before pentobarbital is withdrawn so that the risk of seizure recurrence is minimized. Because pentobarbital is a potent hepatic enzyme inducer, doses of most concurrent anticonvulsants will need to be larger than usual maintenance doses. The patient will need to be monitored for side effects as deinduction occurs and anticonvulsant concentrations increase. This can take up to a month after pentobarbital’s discontinuation.

**Valproate**

Although an IV dosage form has been approved by the FDA, it is not labeled for GCSE. A number of loading and continuous-infusion doses (see Table 66–4) have been used to treat GCSE in both adult and pediatric patients. Loading doses have ranged from 20 to 40 mg/kg.\textsuperscript{25,29} Although the manufacturer originally recommended IV valproate be given no faster than 20 mg/min, much faster rates have been studied (40 mg/min; 2–10 mg/kg/min) and are used for administration of the loading dose.\textsuperscript{25,29} The loading dose should be followed by a continuous or intermittent infusion. One study suggested the need to consider the effects of enzyme-inducing anticonvulsants when dosing and recommended that the continuous-infusion rate be determined by the presence of concurrent anticonvulsants (no inducers present, 1 mg/kg/h; one or more inducers [e.g., phenytoin, phenobarbital], 2 mg/kg/h; and inducers and pentobarbital coma, 4 mg/kg/h).\textsuperscript{30}

In general, IV valproate has been well tolerated, with no cases of respiratory depression. Hemodynamic instability is extremely rare, but patients’ vital signs should be monitored closely during the loading dose.

**Propofol**

Propofol is extremely lipid soluble, has a large volume of distribution, and has a very rapid onset of action. Its extremely short half-life promotes rapid awakening on drug discontinuation. Propofol’s efficacy is comparable to midazolam for refractory GCSE.\textsuperscript{31,41} Doses can be found in Table 66–4. Although controversial, it has been associated with progressive metabolic acidosis, hemodynamic instability, and bradyarrhythmias that maybe refractory to aggressive treatments.\textsuperscript{32} Finally, a normal adult dose can provide over 1,000 calories (4186 J) per day as lipid at a cost to the patient that may exceed $800 per day.

**Other Agents**

In most reports, oral topiramate has been given in adults (300–1,600 mg/day) and in children (5–10 mg/kg/day).\textsuperscript{15,25,33–36} Crushing the tablets and dissolving them in small amounts of water is necessary as no parenteral formulation is available. Doses as large as 25 mg/kg/day for 2 to 5 days have been used in children.\textsuperscript{36} Response tends to be delayed hours to days. Because topiramate can induce metabolic acidosis and kidney stones, monitoring acid–base status and adequate hydration are recommended. Once seizures are controlled, doses should be tapered to a tolerable maintenance dose.

Oral doses of levetiracetam (750–9,000 mg/day) have been given in case series; however, doses larger than 3,000 mg/day do not add additional efficacy.\textsuperscript{15,25,37} IV levetiracetam has begun to replace oral levetiracetam in refractory GCSE. Loading doses of up to 2,000 mg have been given to adults and up to 70 mg/kg in children.\textsuperscript{38–40} Levetiracetam is not heptatically metabolized and is minimally protein bound, which makes drug–drug interactions unlikely. There have been two case reports of lacosamide used in refractory GCSE and NCSE.\textsuperscript{41,42} Like levetiracetam, its lack of effect on the metabolism on other medications make it attractive for use. Neither levetiracetam nor lacosamide has been associated with toxicities (respiratory depression, hypotension) noted with the older anticonvulsants.

Lidocaine has been used in refractory GCSE, but its use is not recommended unless other agents have failed.\textsuperscript{43} It is administered IV and has a rapid onset of action. Table 66–4 gives the recommended initial loading and continuous-infusion doses. Although the reference serum concentration range for the antiarrhythmic effects of lidocaine is 2 to 6 mg/L (8.5–25.6 μmol/L), the reference range for GCSE has not been established. Serum lidocaine concentrations should be monitored to avoid drug accumulation and toxicity. CNS toxicity (e.g., fasciculations, visual disturbances, and tinnitus) can occur at concentrations between 6 and 8 mg/L (25.6 to 34.2 μmol/L); seizures and obtundation can develop when concentrations exceed 8 mg/L (34.2 μmol/L).

Halothane, isoflurane, ketamine, and other inhaled anesthetics can produce EEG suppression; however, these gases are difficult to deliver outside the operating room and require an anesthesiologist. No proven advantages have been shown over traditional anticonvulsants (e.g., barbiturate coma or continuous-infusion benzodiazepine), and these gases can increase intracranial pressure. If used, dosing is titrated to obtain EEG burst suppression. Finally, it is also prudent to validate that the patient does not have a low serum-magnesium concentration, because magnesium deficiency can lower the seizure threshold.

### PHARMACOECONOMIC CONSIDERATIONS

The estimated reimbursement for treatment of GCSE varies greatly based on the age of the individual and the GCSE etiology. A population study showed that the median reimbursement for GCSE was $8,417.\textsuperscript{44} Median reimbursements were significantly greater for those 17 to 45 years of age ($14,689), those with acute CNS injury ($16,919), and those withdrawing from alcohol or anticonvulsants ($11,239). Lowest median reimbursements were found in those 0 to 16 years of age ($6,140) and those with non-CNS injury ($6,669). For patients with lengths of stay shorter than 1 week, the average reimbursement was $7,000 but increased to $32,907 if the stay was longer than 1 week. For patients staying 1 month or more, reimbursements were more than $60,000. Compared with other acute disorders (myocardial infarction, congestive heart failure, and intracranial hemorrhage), reimbursements for GCSE are 1.6- to 1.9-fold greater.

A number of economic issues can have an impact on formulary considerations. Clearly, there are intra- and interclass differences in medication costs and in ancillary tests or technologies associated with select therapies. For example, the average wholesale prices for seven therapies initiated in a patient weighing 70 kg (154 lb) are:

- Diazepam (20 mg) plus generic phenytoin (1 g): $14.68
- Lorazepam alone (8 mg): $6.72
- Midazolam alone (0.25 mg/kg/load, 0.1 mg/kg/h): $51.34
- Generic phenytoin (1 g) alone: $14.34
- Diazepam (20 mg) plus fosphenytoin PE (1 g): $154.14
- Phenobarbital (20 mg/kg) alone: $35.15
- IV valproate (25 mg/kg/load, 1 mg/kg/h): $123.00

Although many practitioners have heralded the arrival of fosphenytoin as an important therapeutic advancement, it has created a
fiscal and ethical dilemma for many institutions. Fosphenytoin is associated with less infusion pain and fewer IV-site complications and hemodynamic adverse effects than phenytoin; however, the cost of this agent ($149/g PE versus $14.47/g phenytoin) has caused many practitioners and administrators to struggle with the practical and ethical importance of the increased safety profile relative to the cost of the product to an institution. When evaluating the difference in cost of these two agents, it is important to remember that phenytoin requires the placement of two IV catheters because of its incompatibility with many solutions and medications that are given concurrently. Additionally, some practitioners are giving fosphenytoin intramuscularly in the emergency room for non-SE indications and thereby avoiding the placement of a catheter and use of an infusion device. Many institutions fail to consider the expense associated with a tissue infiltration of phenytoin, which can cause tissue necrosis that necessitates plastic surgery or amputation. The expense of a single multimillion-dollar lawsuit likely will offset the difference between phenytoin and fosphenytoin cost to several institutions.

There is little difference in expense if one advocates phenobarbital over midazolam as third-line therapy, but it might be argued that a patient who experiences phenobarbital-induced respiration depression ultimately may be more expensive to the healthcare system.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Initial success is defined as termination of all clinical and electrical seizure activity, but ultimate success is measured by the patient’s quality of life. The morbidity and mortality associated with GCSE are affected by the underlying etiology; however, these can be minimized by the rapid implementation of a rational therapeutic plan. An EEG is an extremely important tool that not only allows practitioners to determine when abnormal electrical activity has been aborted but also can assist in determining which anticonvulsant was effective. Because many of the anticonvulsants affect the cardiorespiratory system, it is imperative that vital signs (e.g., heart rate, respiratory rate, and blood pressure) be monitored during drug loading and infusion. Finally, it is imperative that the infusion site be assessed for any evidence of infiltration before and during administration of phenytoin. Information regarding the patient’s past medical and drug history and imaging studies (e.g., MRI) also can help to determine if there is a defined etiology for the original episode of GCSE. This information then can be used to guide future medication therapy, as well as help in determining if the patient is at risk for a poor outcome.

**CONCLUSION**

Our understanding of the cellular basis, physiology, and neuro-pathology of GCSE continues to evolve. Over the past decade, research into an activated cascade of pathophysiologic changes in neurotransmission, GABAergic inhibition, and NMDA receptor channel—mediated events has enhanced our understanding of this disorder. Although anticonvulsants will continue to be the mainstay of therapy in terminating seizures, specific agents including antagonists of excitatory amino acid neurotransmitters (e.g., glutamate and calcium channel blockers) and agonists of inhibitory neurotransmitters (GABA) may help to block further neuronal damage beyond the epileptogenic focus. Likewise, additional trials investigating the role of newer anticonvulsants in GCSE are warranted.
Acute Management of the Brain Injury Patient

BRADLEY A. BOUCHER AND SHELLY D. TIMMONS

1 Cerebral ischemia is the key pathophysiologic event triggering secondary neuronal injury following severe traumatic brain injury (TBI). Intracellular accumulation of calcium is postulated to be a central pathophysiologic process in amplifying and perpetuating secondary neuronal injury via inhibition of cellular respiration and enzyme activation.

2 Guidelines for the Management of Severe Brain Injury, published by the Brain Trauma Foundation/American Association of Neurological Surgeons, serve as the foundation on which clinical decisions in managing adult neurotrauma patients are based; comparable guidelines for infants, children, and adolescents have also been published.

3 Correcting and preventing early hypotension (systolic blood pressure less than 90 mm Hg) and hypoxemia (PaO2 less than 60 mm Hg [8.0 kPa]) are primary goals during the initial resuscitative and intensive care of severe TBI patients.

4 The principal monitoring parameter for severe TBI patients within the intensive care environment is intracranial pressure (ICP). Cerebral perfusion pressure is also a critical monitoring parameter and should be maintained between 50 and 70 mm Hg (greater than 40 mm Hg in pediatric patients) through the use of fluids, vasopressors, and/or ICP normalization therapy.

5 Nonspecific pharmacologic treatment in the management of intracranial hypertension should include analgesics, sedatives, antipyretics, and paralytics under selected circumstances.

6 Specific pharmacologic treatment in the management of intracranial hypertension includes mannitol, furosemide, and high-dose pentobarbital. Neither routine use of corticosteroids nor aggressive hyperventilation (i.e., PaCO2 less than 25 mm Hg) should be used in the management of intracranial hypertension.

7 Phenytoin (or alternatively carbamazepine) should be used to prevent seizures in TBI patients at high risk for the first 7 days after injury. Use of phenytoin for the prophylaxis of posttraumatic seizures usually should be discontinued after 7 days if no seizures are observed.

8 Numerous investigational strategies (e.g., calcium antagonists, glutamate antagonists, antioxidants, free-radical scavengers, and progesterone) targeted at interrupting the pathophysiologic cascade of events occurring following severe TBI have been employed, but no proven therapeutic benefits have been identified.

Traumatic brain injury (TBI) is currently the leading cause of death and disability among children and young adults in the industrialized world. A focus on TBI prevention, and improved acute care and rehabilitation must remain national priorities. This chapter summarizes TBI epidemiology and pathophysiology, and highlights the major guidelines and systematic reviews of the literature pertaining to the management of severe TBI patients.

EPIDEMIOLOGY

It is estimated that approximately 1.4 million persons sustain a TBI each year in the United States. Among these individuals, 235,000 require hospital admission and 50,000 die annually. Importantly, over 5.3 million Americans currently live with disabilities as a result of their TBI, highlighting the enormous physical and emotional toll of this healthcare problem. The economic effects of acute neurotrauma are also enormous, with estimates of spending on TBI patients requiring hospitalization of $60 billion in the United States in 2000. Economic costs to society from lost productivity are also massive, especially considering the young age of many TBI patients. Falls are the leading cause of TBI (28%) while motor vehicle accidents result in the greatest number of TBI-related hospitalizations and deaths overall. Death rates from TBI are highest in patients 75 years of age or older. TBI-related mortality in males has been reported to exceed that in females three-fold. However, recent data suggest that female mortality may actually exceed the mortality rate in males in postmenopausal women.

PRIMARY AND SECONDARY BRAIN INJURY PATHOPHYSIOLOGY

The neurologic sequelae of brain trauma can occur instantaneously as a consequence of the primary injury or can result from secondary injuries that follow within minutes, hours, or days. Primary injury involves the external transfer of kinetic energy to various structural components of the brain (e.g., neurons, nerve synapses, glial cells, axons, and cerebral blood vessels). The biomechanical forces responsible for primary brain injury can be classified broadly as contact (e.g., blunt-object blow, penetrating-missile

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.
injuries and acceleration/deceleration (e.g., instantaneous brain movements following motor vehicle accidents). Primary injuries are categorized further as focal (e.g., contusions, hematomas) or diffuse. The latter usually are associated with shearing or stretch forces, which primarily affect axons within the brain, i.e., diffuse axonal injury). The type of primary injury (i.e., focal versus diffuse) is a major factor as to which of the secondary injury mechanisms discussed below will predominate following a TBI; however, many patients, especially those involved in high-speed accidents sustain both types of injury.

A complex sequence of pathophysiologic events precipitated by primary brain injury may seriously disrupt the normal central nervous system (CNS) balance between oxygen supply and demand. Hypotension during the early posttraumatic period is a central nervous system (CNS) balance between oxygen supply and demand. Factors that can diminish cerebral metabolic demand include cerebral edema, hypoxemia, and temperature elevation. Brain tissue affected by focal ischemia can have a dense core surrounded by a marginally viable region. If adequate CBF is restored, the affected tissue may recover; however, sustained ischemia can result in further loss of cellular integrity and eventual cell death.

The two distinctive end points along the spectrum of secondary neuronal injury are (1) cellular necrosis characterized by cell membrane lysis, edema, and eventual cell death. Necrotic neuronal injury is mediated by N-type voltage-sensitive calcium channels. This calcium influx is postulated to stimulate excessive release of the excitatory amines glutamate and aspartate from the affected neurons. These amines then accumulate in the neuronal synaptic cleft in the presence of cellular energy failure. The result is ongoing stimulation of postsynaptic cells, which can result in an extension of neuro-

FIGURE 67–1. Schematic illustration of the cascade of biochemical events proposed to occur following severe neurotrauma (secondary brain injury). (Ca, calcium; CNS, central nervous system; K, potassium; Mg, magnesium; Na, sodium; Cl, chloride; PMN, polymorphonucleocyte; PG, prostaglandin.)
toxicity and cell death. Influx of calcium and additional sodium is stimulated by activation of ionophore receptors including the N-methyl-D-aspartate (NMDA) receptor. Calcium influx and its intracellular accumulation initiate a number of events that amplify and perpetuate secondary neuronal injury. High intracellular concentrations of calcium result in mitochondrial dysfunction, which further inhibits cellular respiration, a process already affected by ischemic and/or hypoxic insults. A second major deleterious effect of calcium is to stimulate activation of autodestructive enzymes, including phospholipases, endonucleases, and proteases, such as the caspase family of enzymes. The effect of phospholipase A₂ stimulation includes formation of several arachidonic acid metabolites derived from membrane lipids: thromboxane A₂, prostaglandins, and leukotrienes. The subsequent effects of these metabolites are lipid peroxidation and the formation of reactive oxygen species. Recent data suggest that this event occurs very early after injury (e.g., before hospitalization), which may limit the effectiveness of exogenously administered antioxidants.

Cell-mediated injury involving inflammatory mediators (e.g., proinflammatory cytokines) and nitric oxide activation is yet another possible mechanism involved in secondary neuronal injury. Among the cell lines implicated are polymorphonuclear neutrophils, platelets, endothelial cells, and macrophages. Noteworthy is that limited data suggest that activation of some inflammatory mediators may actually be beneficial such that the relative balance of the mediators versus absolute concentrations may be the most significant pathophysiologic factor following TBI. Stimulation of platelet aggregation, vasodilation, and vasoconstriction, intravascularly, also may occur. Lastly, data suggest that there may be a genetic vulnerability to the effects of TBI. For example, preliminary evidence indicates that this may be related to faster recovery of aspartate uptake from the cerebral spinal fluid (CSF) and the CSF lactate/pyruvate ratio in TBI patients in the absence of the apolipoprotein E4 allele. The latter is the same protein that has been associated with the deleterious effects of various types of Alzheimer disease.

CLINICAL PRESENTATION OF ACUTE BRAIN INJURY

**General**
- Level of consciousness on admission ranges from awake and alert to completely unresponsive (i.e., GCS 15 to 3, respectively).

**Symptoms**
- Posttraumatic amnesia (e.g., >1 hour), increasing dizziness, a moderate to severe headache, nausea/vomiting, limb weakness, or paresthesia may indicate more severe injury.

**Signs**
- CSF otorrhea or rhinorrhea, and seizures may indicate more severe injury.
- A rapid deterioration in mental status strongly suggests the presence of an expanding lesion within the skull.
- Severe TBI may be accompanied by significant alterations or instability in vital signs, including abnormal breathing patterns (e.g., apnea, Cheyne-Stokes respiration, tachypnea), hypertension, or bradycardia.

**Laboratory Tests**
- ABGs indicating hypoxia (i.e., decreased \( P_{O_2} \)) or hypercapnia (i.e., increased \( P_{CO_2} \)) may indicate compromised ventilation.

**CLINICAL PRESENTATION**

The Glasgow Coma Scale (GCS) is the most widely used system to grade arousal and the functional capacity of the cerebral cortex. The GCS defines the level of consciousness according to eye opening, motor response, and verbal response (Table 67–1). A GCS score of 15 corresponds to a normal neurologic examination. A GCS score of 3–8, 9–12, and 13–15 is consistent with severe, moderate, and mild brain injury, respectively. The possibility of ethanol or drug intoxication, hypotension, hypoxia, postictal state, or hypothermia altering the neurologic examination always should be considered. Because narcotics and muscle relaxants affect the neurologic examination, they should not be administered until the initial examination is complete if at all possible. Simple, rapidly attainable clinical variables that are predictive of survival include patient age, GCS score (especially the motor score), pupillary reactivity, presence or absence of a hematoma, subarachnoid hemorrhage, midline shift, and appearance of the ventricular cisterns found on a computed tomographic (CT) scan of the head.

General Traumatic Brain Injury Treatment Principles

In July 1995, the Brain Trauma Foundation (BTF) published an extensive document entitled Guidelines for the Management of Severe Brain Injury as a joint initiative with the Guidelines Committee of the American Association of Neurological Surgeons (AANS) and the Joint Section on Neurotrauma and Critical Care of the AANS and the Congress of Neurological Surgeons, with subsequent revision in 2000. A third revision was released in 2007. This landmark publication constitutes the most widely accepted series of evidence-based standards, guidelines, and options for the care of severe TBI patients. As important are the data documenting that compliance with the BTF/AANS guidelines can result in improved outcomes relative to mortality rate, functional outcome scores, length of hospitalization, and cost. Since then, guidelines addressing prehospital TBI management, surgical management, and management of penetrating brain injury have been published. Furthermore, TBI management guidelines for infants, children, and adolescents have been developed. In addition, a series of systematic reviews addressing TBI management emanating from the Cochrane Library has been published. These reviews have rigorously evaluated the literature for essentially all the major conventional TBI treatment strategies. The recommendations emanating from the published guidelines on TBI management and published systematic reviews will be highlighted throughout the remaining portion of this chapter. Until further clinical studies become available, recommendations from the published guidelines should serve as the foundation on which all clinical decisions in managing severe TBI are based. Nonetheless, it should be noted that the majority of the guidelines are based on class II evidence (primarily prospective clinical trials) and class III evidence (primarily retrospective clinical trials). Few class I evidence studies (i.e., prospective, randomized, controlled trials) are available for traumatic brain injury. The pharmacologic management of TBI is summarized in Table 67–2. Recommendations provided in this chapter pertain to adults and children unless specifically noted to the contrary.

### DESIRED OUTCOMES

The overall goal in TBI management is not only reduction in morbidity and mortality but also optimization of long-term functional outcome for these patients. This requires careful attention to the following short-term therapeutic goals: (1) establishment of an adequate airway and maintenance of ventilation and circulation during the initial period of resuscitation and evaluation, (2) maintenance of balance between CDO₂ and CMRO₂, (3) prevention or attenuation of secondary neuronal injury, and (4) prevention and/or treatment of associated medical complications.

### INITIAL RESUSCITATION

The first priority in the unconscious patient is the establishment of an airway, which ensures adequate oxygenation and prevents aspiration. Thereafter, restoration of circulating blood volume and maintenance of systolic arterial pressure (SBP) greater than 90 mm Hg are of utmost importance. In pediatric patients, the SBP goal should be greater than 70 mm Hg + (2 × age in years). Correcting and preventing early hypotension (SBP less than 90 mm Hg) and hypoxia (PaO₂ less than 60 mm Hg [8.0 kPa]) are essential because these two factors are among the most powerful predictors of outcome. Isotonic saline (0.9% normal saline) and lactated Ringer’s solution have been traditionally used as initial resuscitation fluids of choice in TBI patients. However, some clinicians believe that hypertonic saline (e.g., 3% or 7.5% saline) is beneficial in the resuscitation of TBI patients. Clinical studies have yielded equivocal results relative to superiority over isotonic solutions. Regardless, no clear consensus exists as to the optimal initial resuscitation fluid. While albumin therapy may be considered as an alternative to crystalloid fluid resuscitation, a retrospective analysis of 460 TBI patients revealed an increase in mortality (33.2%) compared with those patients receiving 0.9% normal saline. Vasopressors and inotropic agents may be needed to maintain an adequate mean arterial pressure (MAP) if hypotension persists after adequate restoration of intravascular volume. Figure 67–2 is an algorithm summarizing treatment priorities in the initial management of acute TBI.

### POSTRESUSCITATIVE CARE

Following successful resuscitation, priorities shift toward diagnostic evaluation of intracranial and extracranial injuries and emergent surgical intervention as needed. Evacuation of intracranial hematomas (i.e., epidural, subdural, and intracerebral hematomas) is essential to control ICP and improve outcome. Elevation of depressed skull fractures and debриdement of penetrating wound tracts are other important emergent surgical procedures in TBI patients.
Decompressive craniectomies (i.e., removal of variable amount of skull bone) with or without temporal or frontal lobectomy may be considered in patients with increases in ICP refractory to more conservative measures. The beneficial effects of routine decompressive surgery in adult TBI patients to date are controversial. Nonetheless, decompressive surgery in pediatric patients has generally yielded more favorable outcomes.

Continuous ICP monitoring (i.e., intraventricular catheter, intraparenchymal fiberoptic catheter) is indicated in salvageable patients with a GCS score of 3 to 8 after resuscitation with an abnormal admission CT scan, or in high-risk severe TBI patients with a normal CT scan who meet two of the following criteria: age older than 40 years, motor posturing, SBP less than 90 mm Hg. Intraventricular catheters have a therapeutic advantage over the other alternatives but are associated with a higher complication rate and can be difficult to place in the setting of the swollen brain. Specifically, CSF can be drained using this device as a means to lower ICP. Continuous ICP monitoring is the only means to objectively evaluate the success of therapies used to decrease ICP. When the ICP exceeds 20 to 25 mm Hg, therapy should be initiated to decrease ICP below 20 mm Hg. While used extensively in TBI patients and advocated within consensus guidelines, the need for a prospective, randomized, controlled trial to further define its value has recently been suggested. Jugular venous oxygen saturation (SjvO₂) monitoring is advocated by some practitioners for detection of global cerebral hypoxia (i.e., adequacy of CBF relative to CMRO₂), although it is technically difficult to achieve consistent results. Hence its role remains confined predominantly to use in academic centers and for research. The use of brain tissue oxygen monitoring may prove to be a superior alternative to SjvO₂ to evaluate oxygen diffusion in TBI patients.
Cerebral microdialysis is yet another technique that has been used successfully as a research tool to measure the cerebral extracellular chemistry of TBI patients. Biochemical markers (e.g., S-100 protein) have been suggested as having utility relative to monitoring TBI patients. However, no clear role has yet to be defined for such markers, especially since there may be incongruence between serum and brain concentrations of proteins such as S-100.

Another important monitoring parameter for severe TBI patients within the intensive care environment is the cerebral perfusion pressure (CPP). The CPP is the difference between MAP and ICP (i.e., CPP = MAP – ICP). Maintenance of an acceptable CPP has been postulated to be critical in reducing cerebral ischemia and secondary injury. The BTF/AANS guidelines recommend maintaining a range of CPP between 50 and 70 mm Hg and specifically indicate avoiding CPP values less than 50 mm Hg. Current guidelines also recommend that aggressive attempts to maintain CPP greater than 70 mm Hg in adults should be avoided because of the risk of the acute respiratory distress syndrome. In children, the recommended CPP goal is greater than 40 mm Hg. Despite being commonly used, the optimal approach to CPP management continues to be debated.

The goal CPP can be achieved by increasing MAP through the use of fluids and/or vasopressors or by lowering elevated ICP. The goal of volume expansion should be euvoemia as well as avoidance of a hypoosmolar state and negative fluid balance. If the hematocrit is below 30%, transfusion of packed red blood cells (PRBCs) is indicated. However, recent evidence cautions against the liberal use of blood in TBI and other critically ill patients secondary to worse outcomes associated with their use. Volume status should be targeted to a central venous pressure of 7 to 12 cm H2O if invasive monitoring is employed. After achievement of euvoemia, the patient’s head should be elevated at 30 degrees to promote venous drainage and decrease ICP. If restoration of the intravascular volume is inadequate to elevate MAP to an acceptable level, hypertension should be induced using vasopressors or inotropic support. The drugs employed most commonly to induce hypertension are dopamine, phentylephrine, and norepinephrine. Patients should be monitored for renal dysfunction, lactic acidosis, and signs of peripheral ischemia when these agents are used, especially at large doses.

**Treatment of Intracranial Hypertension**

**■ GENERAL PHARMACOLOGIC STRATEGIES**

The use of analgesics, sedatives, and paralytics has an important primary role in the management of intracranial hypertension (Fig. 67–3). This is related directly to the association of pain, agitation, excessive muscle movement, and resisting mechanical ventilation with transient increases in ICP. Nonetheless, there have been no studies of the effect of sedation on outcome in patients with severe TBI. Morphine sulfate is the most commonly used analgesic and sedative in this setting. While fentanyl and sufentanil are gaining in popularity, their use may be associated with mild elevations in ICP. Propofol has become the sedative of choice in TBI patients among many clinicians because of its ease of titration, rapidly reversible effects on discontinuation, and possible neuroprotective effects. Although it is used for sedation in infants and children who are mechanically ventilated in the ICU setting, the Food and Drug Administration (FDA) requires that the manufacturer labeling contain specific information that propofol is not approved for sedation of pediatric patients admitted to an ICU. One of the biggest safety concerns with the use of propofol is the propofol infusion syndrome (PIS) characterized by hyperkalemia, hepatomegaly, lipemia, metabolic acidosis, myocardial failure rhabdomyolysis, renal failure, and death in some cases. While initially reported in children, PIS can also occur in adults. Doses greater than 5 mg/kg/hour and infusion exceeding 48 hours should be used with extreme caution. Triglyceride concentrations also should be monitored in patients receiving prolonged propofol infusions and/or high dosages of propofol considering its lipid emulsion formulation and the potential for inducing hypertriglyceridemia under these conditions. Alternative sedatives include etomidate (particularly useful in rapid-induction anesthesia), intermittent low-dose pentobarbital, and short-acting benzodiazepines (e.g., midazolam), especially if there is a reasonable suspicion of alcohol withdrawal as the underlying etiology of the agitation. The potential for these agents to decrease MAP and CPP must be monitored closely. Additionally, the cumulative sedative effects of longer-acting drugs, especially benzodiazepines, must be taken into account. The use of any sedative agent also must be weighed against its potential to obscure the neurologic examination of the patient. Interference with the neurologic examination is also associated with paralytic agents.

**■ HYPERVENTILATION**

The practice of prolonged aggressive hyperventilation (Paco2 less than 25 mm Hg [3.3 kPa]) to decrease ICP is no longer recommended. Hyperventilation acutely decreases systemic and cerebral PaCO2. The resulting hypocapnia, in turn, induces cerebral vasoconstriction, thereby decreasing CBF and cerebral blood volume (CBV). For decades, it was a widely held belief that a reduction in CBV and any accompanying decrease in ICP were beneficial. Nonetheless, a systematic review of the literature concluded that data are inadequate to ascertain potential benefit or harm from hyperventilation. Hyperventilation should be avoided during the first 24 hours following acute TBI when CBF is often critically reduced according to the most current BTF/AANS guidelines. Hyperventilation for brief periods may nonetheless be considered as a temporary maneuver in the setting of refractory intracranial hypertension or in the initial management of patients with signs of cerebral herniation. If hyperventilation is performed, the use of Svo2 or cerebral tissue oxygen perfusion monitoring is recommended.

**■ HYPOTERMIA**

While hypothermia has been discussed for nearly 50 years as a cerebral protective maneuver in TBI patients, a resurgence of interest has been fueled by the results of several preliminary studies in the early 1990s demonstrating trends in improvement in mortality and morbidity rates in severe TBI patients randomized to receive mild to moderate hypothermia. However, in the most extensive investigation to date, TBI patients randomized to receive hypothermia (n = 199) within 6 hours of injury (target body temperature 33°C [91.4°F]) and maintained for 48 hours did not have significantly improved outcomes at 6 months compared with a normothermia group of TBI patients (n = 196). The BTF/AANS guidelines concur with these findings that prophylactic hypothermia is not significantly associated with decreased mortality when compared with normothermic controls. A recent meta-analysis confirms these results, concluding that hypothermia is not beneficial in the management of TBI patients. Nonetheless, the guidelines leave open the possibility that there may be a mortality benefit if this therapeutic maneuver is continued for more than 48 hours. Depth of hypothermia, as well as the rate of rewarming after discontinuation of hypothermia, are additional factors that may affect outcomes with this therapeutic maneuver in TBI patients. The mechanism underlying a protective effect of hypothermia is likely...
multifactorial, although a reduction in CMRO₂ is offered most frequently as the basis of any therapeutic benefits. Potential side effects of hypothermia include coagulation disturbances, infectious complications, and cardiac arrhythmias.⁶⁶,⁷⁷ An increase in ICP may occur secondary to hypothermia-associated shivering that can be prevented with neuromuscular blocking agents. Unfortunately, these agents are also associated with potential adverse events. Considering these latter risks and equivocal data from clinical trials...

to date, hypothermia should continue to be considered an investigational treatment.26

**OSMOTIC AGENTS**

Although a number of osmotic diuretics (e.g., urea, glycerol) can be used to decrease ICP, mannitol is unquestionably the most widely employed.17,49 Despite the common practice of administering mannitol to patients with suspected or actual increases in ICP following brain injury, no clinical trial comparing its effects against placebo have been performed.27 The mechanisms responsible for mannitol’s beneficial effects likely relate to (1) an immediate plasma-expanding effect that reduces blood viscosity and increases CBF and (2) establishment of an osmotic concentration gradient across an intact blood-brain barrier that decreases ICP as water diffuses from the brain into the intravascular compartment.17 Recommended doses of mannitol typically range from 0.25 to 1 g/kg intravenously every 4 hours.17 Increased ICP is reduced within minutes following mannitol administration, and the duration of action ranges from 90 minutes to 6 hours depending on the dose and the clinical conditions that are present.17 In order to maximize benefit and minimize adverse events, it was previously recommended that mannitol be administered as a bolus and not as a continuous infusion in this setting.1,16 However, recent analyses conclude that neither administration approach has a demonstrable superiority.17,40

Several adverse effects are associated with mannitol. In addition to hypotension resulting from its diuretic effect, a reversible acute renal dysfunction may occur in patients with previously normal renal function after long-term, large-dose administration, especially if the serum osmolality or serum sodium exceed 320 mOsm/kg (mmol/kg) and 160 mEq/L (mmol/L), respectively.1 Hence monitoring and maintaining the serum osmolality and sodium, and replacing urinary fluid losses are important to minimize this adverse event. Mannitol should be avoided in patients with renal failure.21 Acute exacerbation of underlying congestive heart failure and pulmonary edema also may occur following rapid intravascular volume expansion. Furosemide is recommended as an alternative diuretic for lowering ICP in these latter patient groups.

As previously mentioned, hypertonic saline solutions have been advocated as a resuscitative fluid following TBI. Hypertonic solutions ranging from concentrations of 3% to 23.4% have also been used to acutely lower increased ICP.28-31 Not only do hypertonic saline solutions create an osmotic gradient in favor of reducing cerebral edema, but recent evidence suggests that they may also have beneficial vasoregulatory, immunologic, and neurochemical effects as well.11 A comparison of isovolume 20% mannitol versus 7.5% hypertonic saline in 20 TBI patients refractory to nonspecific therapy (i.e., sedation, analgesia, body positioning) demonstrated significant improvement in the duration and number of elevated ICP episodes per day in those treated with 7.5% hypertonic saline.29 No differences in mortality or functional outcome were observed in this study between the two patient groups. However, a recent study of equimolar doses of mannitol versus 7.45% hypertonic saline revealed similar effects between the two regimens in 20 TBI patients.31 As such, demonstration of definitive superiority of hypertonic saline therapy compared with osmotic diuretics will require further investigation.

**BARBITURATES**

High-dose barbiturate therapy (i.e., barbiturate coma) has been used for decades in the management of increased ICP, despite a lack of evidence documenting beneficial effects on patient morbidity and mortality.24 Nonetheless, based largely on beneficial outcomes observed in a randomized clinical trial published in 1988, BTB/ AANS and pediatric guidelines recommend that high-dose barbiturate therapy be considered in hemodynamically stable severe TBI patients refractory to maximal medical ICP-lowering therapy and decompressive surgery.17,22 Prophylactic use of barbiturates is not advocated in light of insufficient evidence supporting this practice and the potential for adverse events (e.g., hypotension).17,21,24 Several mechanisms responsible for the cerebral protective effects of barbiturates have been proposed. These include (1) lowering the regional CMRO₂ with a coupled reduction in CBF to these areas, (2) inhibition of lipid peroxidation, and (3) alteration of cerebral vascular tone.1,40 Prior to inducing a barbiturate coma, the severe TBI patient must be mechanically ventilated with continuous monitoring of arterial blood pressure, electrocardiogram (ECG), and ICP. Pentobarbital is the most commonly used barbiturate for this indication, although thiopental also has been used. Pentobarbital should be administered as an intravenous loading infusion totaling 25 mg/kg (i.e., 10 mg/kg over 30 minutes and then 5 mg/kg per hour for 3 hours), followed by a maintenance infusion of 1 to 2 mg/kg per hour.1,12 If the systolic blood pressure falls during the loading or maintenance infusions, the rate should be slowed temporarily and blood pressure support initiated. The goal of a barbiturate coma is to maintain ICP and CPP at the previously discussed target thresholds in addition to achieving a pentobarbital steady-state concentration of between 30 and 40 mcg/mL (30 and 40 μg/L; 133 and 177 μmol/L) (despite poor correlation between serum concentrations and outcome) and EEG burst suppression.17 Initiation of barbiturate therapy discontinuation can occur when ICP has been controlled satisfactorily for 24 to 48 hours. Barbiturates should be tapered over 24 to 72 hours to prevent ICP spikes.

Side effects associated with high-dose barbiturate therapy involve primarily the cardiovascular system. Hypotension caused by peripheral vasodilation may occur, necessitating decreasing the barbiturate dose or the administration of fluids and vasopressors to maintain blood pressure. A recent systematic review of the literature suggested that one of every four patients receiving barbiturate therapy will develop hypotension.24 Gastrointestinal (GI) effects of barbiturates include decreased GI muscular tone and decreased amplitude of contraction. On emergence from coma, there may be a period of GI hypermotility. Care should be taken to avoid extravasation of pentobarbital and thiopental solutions because severe tissue damage may occur. Barbiturates should be administered by continuous infusion through a central line dedicated for this purpose. The potential for barbiturates to induce the hepatic metabolism of concurrent medications should be also considered. Lastly, the potential for prolonged interference with the proclamation of brain death in TBI patients meeting the locally accepted brain death neurologic criteria must be considered prior to the initiation of high-dose barbiturate therapy.

**CORTICOSTEROIDS**

Although corticosteroids are effective in preventing or reducing cerebral edema in patients with nontraumatic conditions producing vasogenic edema, studies in TBI patients have not demonstrated the ability to lower ICP or improve outcome.17,22 Specifically, use of corticosteroids following TBI has been associated with increased morbidity and complications, including GI bleeding, glucose intolerance, electrolyte abnormalities, and infection. The largest investigation to date was known as the CRASH (Corticosteroid Randomization After Significant Head Injury) study.31 In this study, 10,008 patients with a GCS score less than or equal to 14 were randomized to receive a 48-hour continuous infusion of methylprednisolone or placebo. Results of this study indicated a higher risk of death within 2 weeks of enrollment (relative risk 1.18) in those patients receiving corticosteroids compared with patients receiving placebo
(P <0.001). Based on this and several other major randomized trials, the BTF/AANS adult and pediatric guidelines recommend that high-dose corticosteroids not be used in patients with moderate to severe TBI.

Treatment and Prophylaxis of Complications

■ POSTTRAUMATIC SEIZURES

It is generally agreed that patients who have experienced one or more seizures following a moderate to severe TBI should receive anticonvulsant therapy to avoid increases in CMRO₂, that occur with the onset of subsequent seizures and to prevent the development of (sometimes subclinical) status epilepticus with associated increase in mortality. Initial therapy in these persons should consist of incremental intravenous doses of diazepam (5–40 mg for adults, 0.1–0.5 mg/kg for infants and children) or lorazepam (2–8 mg for adults, 0.03–0.1 mg/kg for infants and children) to terminate any active seizure activity followed by intravenous phenytoin to prevent seizure recurrence. Phenytoin dosing regimens for adults and pediatric patients include an intravenous loading dose of 15 to 20 and 10 to15 mg/kg, respectively, followed by a maintenance dose of 5 mg/kg/day. Alternatively, fosphenytoin, a water-soluble phosphate ester of phenytoin, can be administered intravenously or intramuscularly using the same doses, specified as phenytoin equivalents (PE). The merits of preventive anticonvulsant therapy in patients who have not had a seizure postinjury historically have been more controversial. Risk factors for early posttraumatic seizures (less than 7 days after injury) include a GCS score of less than 10, a cortical contusion, a depressed skull fracture, a subdural hematoma, an epidural hematoma, an intracerebral hematoma, a penetrating head wound, or a seizure within the first 24 hours of injury. In a landmark randomized, placebo-controlled study, the incidence of early posttraumatic seizures in patients receiving placebo was 14.2% compared with 3.6% in patients receiving phenytoin (P <0.05) without a significant increase in drug-related side effects. A systematic review of the literature corroborated these findings, estimating an improved pooled relative risk for early seizure prevention of 0.34 (95% confidence interval, 0.21–0.54) in patients receiving anticonvulsants. Thus it is recommended that phenytoin (or alternatively carbamazepine) should be used to prevent seizures in TBI patients at high risk for the first 7 days after injury. Valproate therapy is not recommended based on a trend for higher mortality in a study comparing valproate-treated patients with those receiving phenytoin short-term therapy. The benefits of prophylactic anticonvulsants beyond 7 days have not been demonstrated, and thus their use for this indication beyond 7 days is not recommended. Unfortunately, despite reducing the incidence of early seizures following brain injury, no beneficial effects have been documented for anticonvulsants on patient mortality or long-term disability. This is particularly disconcerting considering that the long-term risk of epilepsy after TBI has been documented to be increased up to 10 years or longer based on results of a recent population-based cohort study.

■ SUPPORTIVE CARE

While normalizing ICP and maintaining an adequate CPP are the highest priorities in preventing secondary injury following severe TBI, attention also must be given to preventing and/or treating systemic and extracranial complications. This includes careful ongoing fluid and electrolyte management. Common electrolyte disturbances in TBI patients that should be monitored and treated aggressively include hyponatremia, hypomagnesemia, hypokalemia, and hypophosphatemia. Aggressive nutritional support of the TBI patient is another important therapeutic consideration. Evidence suggests that early feeding of TBI patients (i.e., by 7 days) may be associated with a trend toward better outcomes in terms of survival and disability. Infectious complications commonly encountered in severe TBI patients include nosocomial pneumonia, sepsis, urinary tract infections, and meningitis. Treatment of these potentially devastating infections should be aggressive, with careful attention being paid to antibiotic blood–brain barrier penetration for intracranial infections. Hyperthermia also should be avoided in TBI patients because patients with elevated temperatures have poorer outcomes than normothermic patients. Hence aggressive maintenance of a core temperature of less than 37.5°C (99.5°F) using acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), and cooling blankets is indicated for patients following severe TBI. Several experimental cooling techniques, including intravascular cooling for use in TBI patients refractory to conventional management strategies, were discussed in a recent review of this topic. Other important therapeutic interventions include acute gastritis prophylaxis, and prevention of decubiti and contractures. Prevention of thromboembolic events is also an extremely important component of supportive care in TBI patients since the incidence of a deep venous thrombosis is higher in TBI patients compared with patients without brain injury. This can be accomplished with the use of graduated compression stockings or intermittent pneumatic compression devices initially. Therapeutically, systemic therapy (e.g., low-molecular-weight heparin) should generally be initiated within 2 to 3 days in combination with the mechanical devices until patients are ambulatory. However, systemic anticoagulation must be used with caution in those patients with intracerebral hemorrhage, or in patients who may need to undergo craniotomy early in their course. Monitoring for a coagulopathy is important in any severe TBI patient since the incidence is high (greater than 30%), and coagulopathy is associated with a significantly longer ICU length of stay and an almost 10-fold increase in mortality based on data from a recent study. Reversal of coagulopathy with recombinant factor VIIa in critically ill trauma patients with TBI is gaining in popularity among some physicians despite lacking an approved indication or large clinical trials demonstrating its safety and efficacy in TBI patients.

■ CLINICAL CONTROVERSY

Off-label use of recombinant factor VII is advocated by some neurosurgeons for managing life-threatening intracranial hemorrhage in TBI patients. The potential for thromboembolic events using this procoagulant must be considered as part of any cost versus benefit analysis in these patients.

■ CLINICAL PATHWAYS/GUIDELINE IMPLEMENTATION

Use of clinical pathways and formal TBI management guidelines has been demonstrated to improve TBI patient outcomes and reduce institutional resource utilization as summarized in a current review.
The magnitude of these improvements is revealed in a recent single center study in which patients with a good recovery or moderate disability increased from 50.3% to 61.5%, and charges for care were reduced by greater than $8,000.74 Few practitioners would dispute the overall importance of integrating current evidence-based management guidelines into clinical practice as a means to optimize care and improve the functional outcome of TBI patients.66

INVESTIGATIONAL THERAPY

The steady decrease in morbidity and mortality following severe neurotrauma over the last 30 years can be attributed largely to expeditious and aggressive management of events resulting in secondary injury (i.e., ischemia, hypoxia, increased ICP) using conventional treatment strategies. Numerous neuroprotective agents targeting specific pathophysiological processes that are theorized to occur following severe TBI have been investigated over the last decade in an attempt to further enhance the prospects for a meaningful recovery. Prominent among these strategies have been attempts to modulate calcium influx through the administration of calcium antagonists,67,68 and glutamate antagonists including magnesium,69–73 and the use of antioxidants/free-radical scavengers.67 Inhibitors of inflammatory mediators also are under consideration as neuroprotective agents.74 Unfortunately, none of these agents to date has demonstrated a significant reduction in morbidity or mortality following severe TBI in phase III clinical trials. Noteworthy is that a phase II pilot study recently demonstrated a decrease in mortality in 100 TBI patients randomized to receive a 3-day infusion of progesterone compared with placebo.75 A follow-up, independently conducted, double-blinded clinical trial of progesterone in 159 TBI patients also improved outcome at 6 months postinjury,76 prompting experts to call for a phase III trial of this promising pharmacologic strategy.77 Other neuroprotective strategies use growth factors, including brain-derived neurotrophic factor and nerve growth factor,78 that may have a future role in the management of TBI by promoting nerve cell regeneration and differentiation.74 Such neurorestorative strategies can be classified as structural or functional. Lastly, there are miscellaneous agents including calpain inhibitors, inhibitors of caspases (enzymes involved in apoptosis) including erythropoietin and the antiinflammatory agent, minocycline, that are being considered as viable neuroprotective agents based on experimental TBI studies.71,72,78,79 Despite generally negative clinical trial findings to date, the search is likely to continue for neuroprotective agents including those with multiple pathophysiological targets that eventually may improve the long-term outcome in severe TBI patients.80

CLINICAL CONTROVERSY

A growing body of evidence from a small number of studies suggests that beta-blocker use may improve survival following TBI. Mechanistically, these benefits may be realized through reversal of a hyperadrenergic state often associated with TBI. A major concern with their use is the potential to reduce systemic blood pressure.

OTHER TREATMENT STRATEGIES

The concept of administering commercially available CNS active agents for nonapproved indications in TBI patients should presently be considered investigative therapy. One example is the use of CNS stimulants in the management and rehabilitation of TBI patients. A comprehensive review of the use of methylphenidate relative to improving cognition following TBI was recently conducted. It was the opinion of the author that the literature does provide a degree of support for improvements in memory, attention, concentration, and mental processing in this patient subset, although results and study designs were highly variable for those investigations included in the analysis.81 Another example is the use of Parkinson disease medications (e.g., amantidine, bromocriptine, carbidopa/levodopa) in severe TBI patients in an attempt to enhance dopamine release and inhibit reuptake within the injured region of the brain. A review of amantidine following TBI indicated that improved cognition and arousal were evident in the majority of patients studied.82 Cholinergic agents such as donepezil have also undergone limited investigation in TBI patients.83 Antidepressants represent yet another class of agents that has been studied in TBI patients.84

While intuitively appealing, routine administration of psychostimulants to improve cognitive outcomes in TBI patients or drugs that enhance the biochemical milieu within the CNS following a TBI should be undertaken cautiously until large, well-controlled studies demonstrating beneficial effects are available. Additionally, the timing of administration of these drugs is controversial; the potential for cardiovascular side effects in the face of uncertain benefit would indicate that these drugs should be reserved for the postacute phase of treatment (i.e., weeks to months postinjury).

EVALUATION OF THERAPEUTIC OUTCOMES

The process for evaluation of therapeutic outcomes is summarized in Table 67–3. Patients with severe TBI require ICU monitoring initially with the goals of maintaining or reestablishing

<sup>GCS</sup>, Glasgow Coma Scale; BP, blood pressure; HR, heart rate; RR, respiratory rate; CSF, cerebrospinal fluid; TBI, traumatic brain injury; ICP, intracranial pressure; CPP, cerebral perfusion pressure; ABG, arterial blood gas; CBC, complete blood count; Na, sodium; K, potassium; Cl, chloride; Mg, magnesium; Ca, calcium; P, phosphorus; CT, computed tomography.
neurologic and systemic homeostasis as well as readily detecting any neurologic deterioration. This requires frequent evaluation of the patient’s neurologic status (e.g., GCS) and measurement of vital signs, urine output, and arterial oxygen saturation (as well as ICP in patients with an ICP monitor in place). Furthermore, careful attention must be paid to the potential for a variety of electrolyte, mineral, and acid-base disturbances, coagulopathies, and infections by obtaining various laboratory tests on a daily basis initially. The intensity of monitoring will be a function of the relative degree of neurologic and hemodynamic stability of the patient in the hours and days following the neurologic insult. Lastly, radiologic tests (e.g., CT scans) are essential not only for the initial diagnostic evaluation of TBI patients but also as means to evaluate the etiology for any subsequent neurologic deterioration as well.

KEY CONCEPTS

1. Thoughtful consideration for selection of initial therapy, management of drug dosing, and use of adjunctive therapies throughout the course of idiopathic Parkinson’s disease (IPD) is necessary to optimize long-term therapeutic outcomes and minimize adverse effects.

2. The optimal time to start drug therapy in IPD varies, but in general, treatment should be initiated when the disease begins to interfere with activities of daily living, employment, or quality of life. However, in the absence of functional impairment, rasagiline may be offered.

3. Anticholinergic medication is useful for mild tremor-predominant IPD but should be used with caution in the elderly and in those with preexisting cognitive difficulties.

4. As monotherapy, amantadine and monoamine oxidase type B (MAO-B) inhibitors provide benefits in early IPD, but the symptomatic effect is less than that of dopamine agonists and carbidopa/levodopa (L-dopa).

5. Carbidopa/L-dopa is the most effective medication for symptomatic treatment and eventually all patients with IPD will require it.

6. Most carbidopa/L-dopa–treated patients will develop motor complications (e.g., fluctuations and dyskinesias).

7. MAO-B inhibitors and catechol-O-methyl-transferase inhibitors attenuate motor fluctuations in carbidopa/L-dopa–treated patients.

8. Dopamine agonists are effective and, compared to L-dopa, associated with less risk of developing motor complications but more likely to cause psychiatric symptoms, such as hallucinations and impulse control disorders.

9. Surgery is reserved for patients who require additional symptomatic relief or control of motor complications despite receiving medically optimized therapy.

The presence of tremor at rest, rigidity, bradykinesia, and postural instability (instability of balance) are considered the hallmark motor features of idiopathic Parkinson’s disease (IPD). These clinical features of IPD were adeptly described in 1817 by James Parkinson.1

EPIDEMIOLOGY

Up to 1 million individuals in the United States have IPD. The approximate annual incidence of IPD (i.e., number of persons diagnosed with IPD per year) is age-dependent and ranges from 10 per 100,000 persons in the sixth decade of life (i.e., 50–59 years of age) to 120 per 100,000 persons in the ninth decade of life (i.e., 80–89 years of age).2,3 Likewise, the prevalence of IPD also increases with age, affecting 1% of people older than age 65 years and 2.5% of those older than age 80 years. The usual age at time of diagnosis ranges between 55 and 65 years. A higher incidence is reported among males, with a male-to-female ratio of up to 2:1.

ETIOLOGY

The true etiology of IPD is unknown, but is likely the result of interactions between aging, genetic constitution, and environmental factors. In IPD, a key histopathologic feature is degeneration of dopaminergic neurons in the substantia nigra that project to the striatum (i.e., the nigrostriatal pathway).4 Additionally, neuronal vulnerability in IPD extends beyond the nigrostriatal pathway and includes specific neurons in autonomic ganglia, basal ganglia, spinal cord, and neocortex.5 In humans and primates, administration of the compound 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) results in a form of parkinsonism. The MPTP compound is converted by monoamine oxidase (MAO)-B to 1-methyl-4-phenylpyridinium ion (MPP+), a potent neurotoxin. MPP+ is toxic to neurons by inhibiting mitochondrial complex 1 of the electron transport chain, which results in the generation of excessive reactive oxygen species and cell death.6 Several synthetic pesticides have a molecular structure similar to that of MPTP. Although IPD is sporadic, extensive epidemiologic research associates environmental factors, such as chronic exposure to pesticides and heavy metals (such as iron and manganese), rural living, and drinking well water, with a risk for lifetime development of IPD.7–10 Interestingly, epidemiologic studies have consistently associated an inverse correlation between cigarette smoking and caffeine consumption for development of IPD.11,12

Intrinsically, the substantia nigra pars compacta (SNc) is a region characterized by high levels of oxidative stress because free radicals are generated from dopamine autooxidation mediated by MAO (Fig. 68–1). Several antioxidative molecules (e.g., glutathione) are present in the SNc to limit damage produced by free-radical attack,

www.pharmacotherapyonline.com

The complete chapter, learning objectives, and other resources can be found at www.pharmacotherapyonline.com.
but in IPD, such protection might be overwhelmed or impaired. Thus cellular damage from oxidant stress has long been discussed as an etiopathologic component of IPD. The SNc is also rich in iron and copper, essential cofactors in the biosynthesis and metabolism of dopamine. The oxidation–reduction cycle of iron can also generate free radicals and toxic metabolites (Fig. 68–1). In addition, apoptosis (programmed cell death), excitotoxicity, inflammation, mitochondrial dysfunction, nitric oxide toxicity, proteosomal dysfunction, and autaptic cellular mechanisms are also implicated etiopathologic mechanisms in IPD.

Genetics may play a significant role, particularly if IPD begins before age 50 years. More than a dozen gene mutations are associated with forms of parkinsonism. For example, autosomal dominant forms of parkinsonism are associated with mutations of the α-synuclein (PARK1 and PARK4) and leucine-rich repeat kinase 2 (LRRK) genes. Autosomal recessive forms are associated with mutations of parkin (PARK2) and PTEN-induced putative kinase 1 (PINK1) genes. Overall, these forms of genetically linked parkinsonisms constitute only a small percentage of total parkinsonism cases and their pathology and phenotypic aspects differ from that of IPD.

**PATHOPHYSIOLOGY**

In the SNc, the two hallmark histopathologic features of IPD are depigmentation of dopamine-producing neurons (i.e., loss of SNc neurons) and presence of Lewy bodies (neuronal cytoplasmic filamentous aggregates composed of the presynaptic protein α-synuclein) in the remaining SNc neurons. Lewy bodies appear in degenerating neurons in association with adjacent gliosis. Lewy pathology has been proposed to develop in a predictable anatomic distribution within the parkinsonian brain. In the premotor stage of IPD, Lewy bodies are initially found in the medulla oblongata, locus coeruleus, raphe nuclei, and olfactory bulb. This may correlate with observations that anxiety, depression, and impaired olfaction is detectable in premotor stages of IPD. As IPD progresses, Lewy pathology ascends to the midbrain (particularly the SNc) and accounts for development of motor features. In advanced stages, Lewy pathology spreads to the cortex, and this may correlate with cognitive and additional behavior changes. The observation that Lewy pathology can spread into adjacent healthy neurons has given rise to the postulate that prion-like propagation of α-synuclein aggregates may be occurring.

Pathologic findings reveal a correlation between the extent of nigrostriatal dopamine loss and the severity of certain IPD motor features (e.g., bradykinesia). The threshold for onset of clinically detectable IPD appears to be the loss of 70% to 80% of SNc neurons. Functional neuroimaging studies suggest compensatory responses, such as upregulation of dopamine synthesis and downregulation of synaptic dopamine reuptake, occur as adaptive mechanisms beginning in the premotor stage of IPD. These adaptive responses may help to explain why the motor features are not clinically detectable until profound depletion (70%–80%) of SNc neurons has occurred.

Dopaminergic projections from the SNc to the striatum (putamen and caudate) synapse on two major populations of dopamine receptor-mediated efferent neurons (referred to as the direct and indirect pathways), which, in turn, mediate motor activity via a complex neuronal circuit involving the extrapyramidal system (Fig. 68–2). In IPD, the degeneration of the SNc neurons results in reduced activity within these two efferent pathways. The direct pathway involves activation of striatal dopamine receptors (which are coupled to adenylate cyclase) and stimulates...
inhibitory to the thalamus. In IPD, the reduced activation of D2 receptors translates into greater inhibition of the thalamus. In IPD, restoring activity at the D2 receptor appears to be of more importance than the D1 receptor for mediating clinical improvements. Overall, loss of the presynaptic nigrostriatal dopamine neurons in IPD results in inhibition of thalamic activity and reduced activation of the motor cortex. Dopaminergic therapies help to restore motor activity.

In addition to dopamine, the synaptic organization of the basal ganglia also involves a variety of other neurotransmitters and neuromodulators, including acetylcholine, adenosine, enkephalins, GABA, glutamate, serotonin, and substance P. The potential role for drug modulation of these other neurotransmitters and receptor types is an active area of research and novel drug discovery for IPD. Atypical parkinsonian disorders, such as multiple system atrophy and progressive supranuclear palsy are characterized by damage to postsynaptic striatal neurons and dopamine receptors. Dopaminergic therapies provide less robust efficacy in atypical parkinsonism.

### CLINICAL PRESENTATION

Although IPD is unmistakable in its advanced form, recognizing IPD during the early stages can be challenging. Clinically probable IPD can be diagnosed when at least two of the following are present: limb muscle rigidity, resting tremor (at 3–6 Hz and abolished by movement), or bradykinesia (Table 68–1). Asymmetry in the presence or severity of these motor features is also a conspicuous finding. Overall, a diagnosis of IPD can be made with a high level of confidence in a patient who has resting tremor (along with bradykinesia and/or rigidity), prominent asymmetry, and a good response to dopaminergic therapy. For the diagnosis of IPD, other conditions must be reasonably excluded (Table 68–1). Medication-induced parkinsonism can mimic IPD, so it is important to establish if such medications have been used (especially drugs that block D2 receptors, such as antipsychotics, metoclopramide, or phenothiazine antiemetics). Neurologic conditions that can be mistaken for IPD include atypical parkinsonisms (e.g., corticobasal ganglionic degeneration, forms of multiple system atrophy, progressive supranuclear palsy) and essential tremor. Because the management and prognosis of IPD differs from these other conditions, an accurate diagnosis is important. When the diagnosis is in doubt, referral to a movement disorders specialist is recommended.

### PRESENTATION OF IDIOPATHIC PARKINSON’S DISEASE

#### General Features

- For clinically probable IPD, the patient exhibits at least two of the following: resting tremor, rigidity, or bradykinesia. Asymmetric onset and severity of these features is typical.

- Postural instability (difficulty with maintaining balance) is more common in advanced IPD.

#### Motor Symptoms

- The patient experiences decreased manual dexterity, difficulty arising from a seated position, diminished arm swing during ambulation, dysarthria (slurred speech), dysphagia (difficulty with swallowing), festinating gait (tendency to pass from a walking to a running pace), flexed posture (axial, upper/lower extremities), “freezing” at initiation of movement, dysphonia (reduced voice volume), and micrographia (diminution of handwritten letters/symbols) (Fig. 68–3).

#### Autonomic and Sensory Symptoms

- The patient experiences bladder and anal sphincter disturbances, constipation, diaphoresis, fatigue, olfactory disturbance, orthostatic blood pressure changes, pain, paresthesia, paroxysmal vascular flushing, sialorrhea, sexual dysfunction, and salivation.

#### Mental Status Changes

- No laboratory tests are available to diagnose IPD.

#### Other Diagnostic Tests

- Genetic testing is not routinely helpful.
- Neuroimaging may be useful for excluding other diagnoses.
- Medication history should be obtained to rule out drug-induced parkinsonism.

IPD develops insidiously and progressively worsens. Over many years, symptoms generally worsen to the point of severe disability, necessitating placement in a skilled nursing facility (especially with the development of dementia or frequent falling). However, in a subset of patients, clinical symptoms remain stable for many years. Tremor of an upper extremity occurring at rest (and occasionally a postural tremor) is often the sole presenting complaint; however, only two-thirds of patients with IPD have tremor on diagnosis, and some never develop this sign. Tremor in IPD is present most commonly in the hands, sometimes with a characteristic pill-rolling motion. Less commonly, tremor may involve the jaw, legs, and toes. Like other motor features of IPD, resting tremor often begins unilaterally and becomes bilateral with disease progression. Stressful or emotional (either negative or positive) situations often increase the tremor amplitude and severity. Usually, volitional movement abolishes resting tremor, and tremor is absent during sleep. Although resting tremor is visibly noticeable in IPD and may cause social embarrassment for the patient, it often is the least physically disabling of the motor features.

Rigidity is the increased muscular resistance to passive range of motion and commonly affects the upper and lower extremities. If tremor is present in the affected extremity, the rigidity is associated with a cogwheel or ratchet-like quality upon examination. Facial muscles also are affected, resulting in hypomimia (masking of facial expressions) that may be erroneously interpreted as apathy, depression, or unfriendliness.

Bradykinesia refers to slowness of movement. Movement in IPD is often slow throughout an intended action, and difficulty with the
Neurologic Disorders

SECTION 6

Postural instability, most common in advanced stages of IPD, is one of the most disabling problems of IPD because it increases the fall risk and is least amenable to pharmacotherapy. Testing for impaired postural responses by means of the pull test (in which a patient is unable to recover balance after sudden backward displacement at the shoulders) can help to identify the risk for falling. Many patients with impaired postural responses also have tendencies for propulsive gait (festination) and freezing, which also increases the risk of falling.

Although IPD is known predominantly as a disorder of motor capabilities, neuropsychiatric abnormalities also develop. Intellectual deterioration is not inevitable in IPD; however, some patients deteriorate in a manner indistinguishable from Alzheimer disease and other dementing conditions. 20 IPD patients are also at increased risk for anxiety and depression. 21 Although the disabilities of IPD may provoke depression in some instances, the underlying biochemical changes in the brain associated with IPD pathophysiology also predispose for endogenous depression.

TREATMENT

### DESIRED OUTCOMES

The goal in the management of IPD is to improve motor and nonmotor symptoms so that patients are able to maintain the best possible quality of life.22 Specific objectives to consider when selecting an intervention include preservation of the ability to perform activities of daily living; improvement of mobility; minimization of adverse effects, treatment complications, putative disease modification; and improvement of nonmotor features such as:

- Initiation of movement also occurs. A progressive slowing and decline in dexterity may impair tasks such as hand clapping, finger tapping, and handwriting (Fig. 68–3). Intermittent immobility (freezing) is another common characteristic. Freezing is especially likely to occur in situations such as when walking through a narrow doorway or initiating a turn. Patients also may experience a slow shuffling gait with difficulty halting their steps while in motion (festinating gait).

### TABLE 68-1 Diagnostic Criteria for Idiopathic Parkinson’s Disease and Differential Diagnosis

<table>
<thead>
<tr>
<th>Idiopathic Parkinson’s disease</th>

<tbody>
<tr>
<td>Clinically possible: Presence of one of the following: resting tremor, rigidity, or bradykinesia</td>
</tr>
<tr>
<td>Clinically probable: Presence of at least two of the following: resting tremor, rigidity, or bradykinesia</td>
</tr>
<tr>
<td>Clinically definite: Presence of at least two of the following: resting tremor, rigidity, or bradykinesia and a positive response to antiparkinsonian pharmacotherapy</td>
</tr>
</tbody>
</table>

Differential diagnosis

- Essential tremor
- Secondary parkinsonism
- Pharmacotoxicity (drug induced)
  - Antiparkinsonians (e.g., metoclopramide, prochlorperazine)
  - Antipsychotics (e.g., phenothiazines, haloperidol, olanzapine, risperidone)
- Other drugs (α-methyldopa, cinnarizine, flunarizine, tetrabenazine)
- Environmental toxicity
  - Carbon monoxide poisoning
  - Manganese
  - Methanol
  - MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine)
  - Organophosphates
  - Infections
    - Human immunodeficiency virus–associated parkinsonism
    - Postencephalitic parkinsonism
    - Subacute sclerosing panencephalitis
- Metabolic disorder
  - Hypothyroidism
  - Hyperparathyroidism
- Paraneoplastic abnormalities
- Neoplasms, strokes, traumatic lesions involving the nigrostriatal pathways
- Normal-pressure hydrocephalus
- Parkinsonism with other neuronal system degenerations
- Alzheimer with parkinsonism
- Corticobasal ganglionic degeneration
- Creutzfeldt-Jakob disease (CJD)
- Dementia with Lewy bodies
- Frontotemporal dementia
- Progressive supranuclear palsy
- Multiple-system atrophy
- Striatonigral degeneration
- Shy-Drager syndrome
- Olivopontocerebellar atrophy
- Familial (hereditary) parkinsonism
- Autosomal dominant
  - α-Synuclein gene mutation (PARK1 and PARK4)
  - Frontotemporal dementia parkinsonism (FTDP-17)
  - Levodopa responsive dystonia
  - Leucine-rich repeat kinase 2 (LRRK2) mutation
  - Rapid-onset dystonia parkinsonism (DYT12)
  - Spino cerebellar ataxia (SCA2, SCA3)
- Autosomal recessive
  - Pantothenate kinase-associated neurodegeneration (PKAN)
  - Niemann Pick type C
  - Wilson disease
  - Young-onset parkinsonism (DJ-1, parkin, PINK1)
- X-linked recessive
  - Fragile X tremor/ataxia syndrome (FXTAS)
  - Lubag (DYT3 or Filipino dystonia parkinsonism)
  - Waisman syndrome (X-linked parkinsonism with mental retardation)

Postural instability, most common in advanced stages of IPD, is one of the most disabling problems of IPD because it increases the fall risk and is least amenable to pharmacotherapy. Testing for impaired postural responses by means of the pull test (in which a patient is unable to recover balance after sudden backward displacement at the shoulders) can help to identify the risk for falling. Many patients with impaired postural responses also have tendencies for propulsive gait (festination) and freezing, which also increases the risk of falling.

Although IPD is known predominantly as a disorder of motor capabilities, neuropsychiatric abnormalities also develop. Intellectual deterioration is not inevitable in IPD; however, some patients deteriorate in a manner indistinguishable from Alzheimer disease and other dementing conditions.20 IPD patients are also at increased risk for anxiety and depression.21 Although the disabilities of IPD may provoke depression in some instances, the underlying biochemical changes in the brain associated with IPD pathophysiology also predispose for endogenous depression.

### FIGURE 68-3. Example of micrographia in a patient with IPD. As the sentence, “Today is a sunny day in California” is repeatedly handwritten, progressive diminution of letter size occurs (micrographia). The height of each lined row is approximately 5/16 inches (8 mm). (Courtesy of Jack J. Chen, PharmD, and David M. Swape, MD.)
cognitive impairment, depression, fatigue, and sleep disorders. To accomplish some of these objectives, consultation with a specialist is helpful (e.g., movement disorders, physical therapy, psychiatry, and sleep medicine).

### General Approach to Treatment

1. Once a correct diagnosis of IPD is made, nonpharmacologic and pharmacologic interventions must be considered. Figure 68–4 illustrates a general treatment approach for early and advanced IPD and Table 68–2 summarizes antiparkinsonian medications and mechanisms of action. Treatment guidelines and monographs are updated frequently to keep up with new information and changes in treatment paradigms.23–28

2. In the absence of functional impairment, initial monotherapy may be initiated with an MAO-B inhibitor, such as rasagiline, with the addition of other therapeutic agents as IPD motor symptoms progressively worsen. Therapy with rasagiline in early stage PD has been demonstrated to slow the decline of motor function and is well tolerated. The definition of functional impairment is highly patient specific. Factors such as comorbid conditions, cognitive status, employment, lifestyle, and patients’ desires must be considered when initiating pharmacotherapy.

In a “physiologically” young patient experiencing functional impairment, monotherapy with a dopamine agonist or rasagiline is preferred. For patients who are older, cognitively impaired, or experiencing moderately severe functional impairment, L-dopa (e.g., carbidopa/levodopa) is preferred. Ultimately, all patients will require the use of L-dopa (either as monotherapy or in combination with other agents). With the development of motor fluctuations, addition of a catechol-O-methyltransferase (COMT) inhibitor should be considered to extend L-dopa duration of activity, or if the patient is not already on an MAO-B inhibitor or dopamine agonist, addition of either one should be considered. For management of L-dopa induced peak-dose dyskinesias, the addition of amantadine should be considered. Surgery is considered only in patients who need more symptomatic control or who are experiencing severe motor complications despite pharmacologically optimized therapy.

The treatment plan evolves as the disease progresses and must include consideration of short-term symptomatic relief as well as long-term effects. Patient specific factors that guide selection of therapies include the “functional” age of the patient, patient’s desired outcomes, cognitive status, severity of motor features, and response to any previous IPD therapies. Patient education should be communicated with realistic optimism. For example, it
should be explained that although there is no cure for IPD, modern medicine has many medications that can provide relief of symptoms. Nonpharmacologic interventions such as exercise should be encouraged, and attention to nonmotor features of IPD should not be neglected.

### PHARMACOLOGIC THERAPY

#### Anticholinergic Medications

Because dopamine provides negative feedback to acetylcholine neurons in the striatum, the degeneration of nigrostriatal dopamine neurons also results in a relative increase of striatal cholinergic interneuron activity. This increased cholinergic activity (caused by dopamine depletion) is believed to contribute to the tremor of IPD. The anticholinergic drugs (e.g., benztropine and trihexyphenidyl) are considered effective against tremor but no more than dopaminergic agents. 23 – 25 Sometimes dystonic symptoms of IPD. The anticholinergic drugs (e.g., benztropine and trihexyphenidyl) are considered effective against tremor but no more than dopaminergic agents.

#### Amantadine

Amantadine provides modest symptomatic benefit for tremor, as well as rigidity and bradykinesia. The precise mechanism of action of amantadine is unknown, but dopaminergic and non-dopaminergic mechanisms, such as inhibition of glutamatergic N-methyl-D-aspartate (NMDA) receptors, are implicated. Amantadine is typically administered 300 mg/day in divided doses. Amantadine is also useful for suppressing l-dopa-induced dyskinesia. 27 The antidysesthetic properties of amantadine are presumed to be mediated by antiglutamate activity which, in the setting of dyskinesias, appears to dominate over dopaminergic activity. Amantadine is eliminated renally, and a reduced dose should be administered when renal dysfunction is present (100 mg/day with creatinine clearances of 30–50 mL/min (0.50 to 0.84 mL/s), 100 mg every other day for creatinine clearances of 15–29 mL/min (0.25 to 0.49 mL/s), and 200 mg every 7 days for creatinine clearances of less than 15 mL/min (0.25 mL/s), and patients on hemodialysis).

Common side effects of amantadine include confusion, dizziness, dry mouth, and hallucinations. The elderly are particularly prone to develop confusion. Not uncommonly, amantadine may cause livedo reticularis, a reversible condition characterized by diffuse mottling of the skin affecting the upper or lower extremities and often accompanied by lower-extremity edema.

#### Carbidopa/L-Dopa

L-Dopa is the immediate precursor of dopamine and, in combination with a peripherally acting l-amino acid decarboxylase inhibitor (carbidopa or benserazide), remains the most effective drug for the symptomatic treatment of IPD. 23–25 L-Dopa crosses the blood–brain barrier, whereas dopamine, carbidopa, and benserazide do not. The combination of L-dopa with carbidopa or benserazide, reduces the unwanted peripheral conversion of L-dopa to dopamine. As a result, increased amounts of L-dopa are transported into the brain, and peripheral adverse effects of dopamine, such as nausea, are reduced. In the SNc, l-dopa is converted, via decarboxylation, to dopamine by the enzyme l-amino acid decarboxylase (Fig. 68–5). The converted dopamine is stored in the presynaptic SNc neurons until stimulated to be released into the synaptic cleft whereupon it binds to the D1 and D2 postsynaptic receptors. Dopamine activity is terminated primarily by reuptake back into the presynaptic neuron by means of a dopamine transporter. The enzymes MAO and COMT also inactivate dopamine.

Regardless of what the initial therapeutic agent is, ultimately all patients with IPD will require L-dopa at some point. An initial maintenance L-dopa regimen of 300 mg/day (in divided doses and in combination with carbidopa or benserazide) often is adequate. With regard to carbidopa, about 75 mg/day is required to sufficiently inhibit the peripheral activity of L-amino acid decarboxylase, but some patients require more. Therefore, the usual initial maintenance carbidopa/L-dopa regimen is 25/100 mg 3 times daily. As the motor features of IPD become progressively more severe, use of higher dosages is required. There is no maximum allowable total daily L-dopa dose; however, the usual maximal dose needed by patients, even those with severe IPD, is 800 to 1,000 mg/day. Slow buildup of dose (e.g., increments of 100 mg L-dopa per week) can help to minimize treatment emergent side effects, such as nausea, postural hypotension, sedation, vivid dreaming, and vomiting.
For patients with difficulty swallowing tablets, an orally disintegrating tablet preparation of carbidopa/L-dopa is available. Although this formulation rapidly dissolves on contact with saliva, the carbidopa/L-dopa does not undergo transmucosal absorption and must reach the proximal duodenum for absorption.

**Pharmacokinetics** There is marked intra- and intersubject variability in the time to peak plasma concentrations after oral L-dopa, and this may in part be attributed to differences in gastric emptying. L-Dopa is absorbed primarily in the proximal duodenum by a saturable large neutral amino acid transport system. Competition for this transporter by dietary or supplemental large neutral amino acids (e.g., leucine, phenylalanine) can interfere with L-dopa bioavailability.

L-Dopa is not bound to plasma proteins. Active transport across the blood–brain barrier occurs by the large neutral amino acid transporter system. Because large amounts of dietary large neutral amino acids may compete for transport across the blood–brain barrier and interfere with the clinical response to L-dopa, separation of L-dopa administration with high protein meals has been recommended. However, in patients with early IPD, this interaction is generally not significant. In advanced IPD, special diets involving protein restriction or redistribution may improve L-dopa responsiveness and are sometimes implemented. A metabolite of L-dopa, 3-O-methyl-L-dopa, also competes for transport, but it is not clear how this affects L-dopa clinical response.

When peripheral decarboxylation of L-dopa is inhibited by carbidopa or benserazide, 3-O-methylation (via COMT) becomes the predominant catabolic pathway. The elimination half-life of L-dopa is about 1 hour, and this is extended to about 1.5 hours with the addition of carbidopa or benserazide. With the addition of a COMT inhibitor such as entacapone to carbidopa/L-dopa, the elimination half-life is extended to about 2 to 2.5 hours.

### Motor Complications of L-Dopa

Long-term L-dopa therapy is associated with a variety of motor complications, of which end-of-dose “wearing off” (motor fluctuations) and L-dopa peak-dose dyskinesias are the two most commonly encountered. These motor complications can be disabling and challenging to manage. The approximate risk of developing either motor fluctuations or dyskinesia is 10% per year of L-dopa therapy. However, motor complications can occur as early as 5 to 6 months after starting L-dopa therapy, especially if excessive doses are used initially. Table 68–3 lists the motor complications associated with long-term treatment with L-dopa and suggested initial management strategies. Initiating therapy with the controlled-release form of carbidopa/L-dopa does not reduce the development of motor complications compared with standard-release carbidopa/L-dopa.

#### End-of-Dose Wearing Off

The terms “off” and “on” refer to periods of poor movement (i.e., return of tremor, rigidity, or slowness) and good movement, respectively. End-of-dose wearing off prior to a dose of medication is a common type of response fluctuation. This phenomenon is related to the increasing loss of neuronal storage capability for dopamine as well as the short half-life of L-dopa. Initially, exogenous L-dopa is taken up by the remaining SNc neurons, converted to dopamine, and stored in synaptic vesicles. With progressive loss of SNc neurons, storage capacity, and synthesis of endogenously derived dopamine, patients become more dependent on exogenous L-dopa. Hence the peripheral pharmacokinetic properties of L-dopa increasingly become the determinant of central dopamine synthesis. With advancing IPD, the duration of action of a single carbidopa/L-dopa dose progressively shortens, and in some cases may produce benefits for as little as 1 hour. As a result, carbidopa/L-dopa needs to be given more frequently so as to minimize daytime off episodes and to maximize on time. In addition to administering L-dopa doses more frequently, other options are available (see Table 68–3). In particular, the addition of the COMT inhibitor entacapone or the MAO-B inhibitor rasagiline extends the action of L-dopa, and either should be considered. A controlled-release (CR) L-dopa product is available, but is not considered very effective for management of motor fluctuations.

A dopamine agonist (e.g., pramipexole, ropinirole) also can be added to a carbidopa/L-dopa regimen in an attempt to minimize the occurrence of wearing off. For acute off episodes, a subcutaneously administered short-acting dopamine agonist, apomorphine, is available and possesses a rapid onset of effect (within 20 minutes). It is administered as needed. Alternatively, chronic subcutaneous apomorphine infusion (not yet available in the United States) provides stable and continuous systemic and central drug concentrations and improves motor fluctuations and dyskinesias. Long-term therapy is limited by injection site skin reactions. In addition, intraduodenaljejunal L-dopa infusions produce constant and smoother stimulation of striatal dopamine receptors and thus stabilize response fluctuations. An infusible duodenal carbidopa/L-dopa gel (not yet available in the United States) has been demonstrated.

COMT, catechol-O-methyltransferase; CR, controlled release; MAO, monoamine oxidase; ODT, orally disintegrating tablet.
to be an effective and safe therapy, and, as with subcutaneous apomorphine infusion, would be considered a last-line pharmacologic therapy for patients with persistent, on/off fluctuations. Although not commonly performed, sipping small amounts of carbidopa/l-dopa solution very frequently throughout the day is also a method for managing on/off fluctuations. A solution that is stable for 72 hours at room temperature can be prepared by adding 10 tablets of carbidopa/l-dopa 10/100 (or 25/100) mg and 2 g crystalline ascorbic acid to 1 L of water.

Often, off episodes occur during the night, and patients will awaken in an off state (as a consequence of an overnight decline of drug levels). Bedtime administration of a dopamine agonist or a drug formulation that provides sustained drug levels overnight (e.g., carbidopa/l-dopa CR, ropinirole XL, pramipexole ER) can help reduce nocturnal off episodes and improve functioning upon awakening.

"Delayed-On" and "No-On" Response. "Delayed-on" or "no-on" (a delayed or absent onset of drug effect, respectively) responses to individual doses of carbidopa/l-dopa can be a result of delayed gastric emptying or decreased absorption in the duodenum. Chewing a tablet or crushing it and then drinking a full glass of water, or using the orally disintegrating tablet formulation on an empty stomach, can help mitigate effects of delayed gastric emptying. Additionally, subcutaneously administered apomorphine may be used as rescue therapy from delayed-on or no-on periods. A drug-free period ("drug holiday") has been investigated in an attempt to modify postsynaptic dopamine receptors and thus decrease unpredictable off states. Although not commonly performed because of discomfort (to the patient) and medical risks, when drug holidays are performed, it should be under close medical supervision.

Freezing. "Freezing," or a sudden, episodic inhibition of lower-extremity motor function, may occur and will interfere with ambulation and increase the risk of falls. Patients may report that their "feet suddenly feel stuck to the floor" during ambulation or that they have difficulty initiating steps (start hesitation) or turns (turn hesitation). Freezing often is exacerbated by anxiety or when perceived obstacles (e.g., doorways, turnstiles) are encountered. Although changes to the antiparkinson drug regimen may be warranted, improvements are unlikely. Physical therapy along with assistive walking devices and sensory cues are helpful.

Dyskinetias. Another complication of l-dopa therapy is "on" period dyskinetias (involuntary choreiform movements involving usually the neck, trunk, and lower/upper extremities). If patients report "shakiness," it is important to clarify if they are referring to tremor or dyskinetias. Dyskinetias usually are associated with peak striatal dopamine levels (peak-dose dyskinetias) and, simplistically, can be thought of as too much movement secondary to extension of the pharmacologic effect resulting in excessive striatal dopaminergic receptor stimulation. Less commonly, dyskinetias also can develop during the rise and fall of l-dopa effects (the dyskinetia–improvement–dyskinetias or diphasic pattern of response). In the case of peak-dose dyskinetias, use of lower individual doses of l-dopa is beneficial. With the lowering of the l-dopa dose, dyskinetias improve but at the cost of returning parkinsonian features, thereby necessitating an increase in dosage frequency or addition of another agent to counteract the effects of using a lower l-dopa dose. Glutamate overactivity may also be involved as suggested by the antidyskinetia effect of amantadine (NMDA receptor antagonist) and positive results of investigational studies of antiglutamate ligands in animal models. For severe dyskinetias (despite pharmacologically optimized therapy), surgery should be considered.

"Off-Period" Dystonia. In IPD, dystonias (sustained muscle contractions) can occur and more commonly affect a distal lower extremity (e.g., clenching of toes or involuntary turning of a foot). Dystonias often occur in the early morning hours (as a result of waning drug levels) and improve with the first l-dopa dose of the day. Remedies for early morning dystonia include bedtime administration of a long acting dopamine agonist, sustained-release carbidopa/l-dopa, baclofen, or focal injections of botulinum toxin (for persistent focal dystonia).

**CLINICAL CONTROVERSY**

The question of when to initiate l-dopa therapy is a matter of debate. Generally, initial therapy with a non–l-dopa agent is often recommended for patients younger than 65 years of age. Proponents for initiating non–l-dopa agents first and then adding l-dopa at a later point, cite evidence suggesting that long-term l-dopa therapy is associated with an increased risk of motor complications that can be disabling and challenging to manage. Additionally, drugs such as rasagiline and dopamine agonists provide sufficient symptom control for mild to moderate IPD. The counterargument is that l-dopa is inexpensive, more effective, and the development of motor complications is an acceptable trade-off. Age alone should not be the major deciding factor, and ultimately, individualized considerations of a patient’s disability should guide all interventions for IPD.

**Monoamine Oxidase B Inhibitors**

Two selective MAO-B inhibitors, rasagiline and selegiline, are available in the United States for management of IPD. The selective inhibition of MAO-B in the brain interferes with the degradation of dopamine and results in prolonged dopaminergic activity. Both drugs contain a propargylamine moiety, which is essential for conferring irreversible inhibition of MAO-B. At therapeutic doses, these agents preferentially and irreversibly inhibit MAO-B over MAO-A.

A common concern with use of these agents is the potential for interactions with drugs that possess serotonergic activity. Concomitant use of MAO-B inhibitors with meperidine and other selected opioid analgesics is contraindicated because of a small risk of serotonin syndrome. However, concomitant use of other agents that enhance serotonin levels (e.g., antidepressants) is not contraindicated and can be used concomitantly when clinically warranted.

Selegiline, also known as l-deprenyl, is marketed for extending l-dopa effects and is typically administered 5 mg twice daily. Selegiline is also available as an orally disintegrating tablet formulation administered 1.25 to 2.5 mg once daily. A transdermal formulation of selegiline is also available but is not indicated for IPD. As monotherapy in early IPD, conventional selegiline provides modest improvements in motor function. In more advanced IPD, the adjunctive use of conventional selegiline can provide up to 1 hour of extended on time for patients with wearing off, although the data are inconsistent. This inconsistent effect of conventional selegiline may be explained, in part, by poor and erratic bioavailability of the parent drug.

As an amphetamine pharmacophore, selegiline undergoes first-pass hepatic metabolism (predominantly via cytochrome P450 [CYP] 2B6 and 2C19) to end products of l-methamphetamine and l-amphetamine. Adverse effects of selegiline are minimal but can include insomnia (especially if administered at bedtime), hallucinations, and jitteriness. Selegiline also increases
the peak effects of l-dopa and can worsen preexisting dyskinesias or psychiatric symptoms such as delusions. With the selegiline orally disintegrating tablet formulation, first-pass hepatic metabolism is bypassed as a consequence of transmucosal absorption of the drug. Hence, bioavailability characteristics of the parent drug are improved and formation of amphetamine metabolites is reduced. Thus, the selegiline orally disintegrating tablet formulation may provide an improved response relative to conventional selegiline.

Rasagiline is a second-generation, irreversible, selective MAO-B inhibitor administered at 0.5 or 1 mg once daily. Rasagiline is effective as monotherapy in early IPD and also as add-on therapy for managing motor fluctuations in advanced IPD. In a large, placebo-controlled, 18-month, delayed-start clinical trial, patients initiated on rasagiline mono-therapy early in IPD had less functional decline than did patients whose treatment was delayed for 9 months. This suggests that earlier initiation with rasagiline (even before the onset of functional impairment) is associated with better long-term outcomes. For the management of patients with motor fluctuations, the efficacy of rasagiline appears similar to that of entacapone, offering approximately 1 hour of extra on time during the day. Consequently, when an adjunctive agent is required for managing motor fluctuations, rasagiline is considered a first-line agent (as is entacapone).

Overall, rasagiline is well tolerated with minimal gastrointestinal or neuropsychiatric side effects. Rasagiline is metabolized by hepatic CYP1A2 to aminoindan, which is inactive and devoid of amphetamine-like properties.

MAO-B inhibitors with a propargylamine molecular scaffolding have been investigated for neuroprotective properties (clinically referred to as disease modification). These agents inhibit the oxidative deamination of dopamine, which generates hydrogen peroxide and, ultimately, oxyradicals capable of damaging nigrostriatal neurons (see Fig. 68–1). Because MAO-B inhibition diverts dopamine catabolism to an alternate route that does not generate peroxide, MAO-B inhibitor therapy may spare neurons from oxidative stress. Additionally, MAO-B inhibitors have demonstrated antiapoptotic properties in laboratory experiments, further suggesting the possibility of disease modification. Clinical studies to demonstrate disease modification with selegiline have yielded inconclusive results, perhaps contributed in part by selegiline amphetamine metabolites as well as inadequate study methodology. However, results with rasagiline 1 mg/day from clinical studies utilizing methodology consistent with selegiline have yielded inconclusive results, perhaps contributed in part by selegiline amphetamine metabolites as well as inadequate study methodology. However, results with rasagiline 1 mg/day from clinical studies utilizing methodology (i.e., delayed start) to demonstrate disease modification have been positive.

**CLINICAL CONTROVERSY**

Great interest and debate surround the putative disease modifying effects of the MAO-B inhibitors. To date, only rasagiline has been shown to slow the rate of progression of motor impairment in patients with early IPD. A large clinical study demonstrated that earlier initiation of rasagiline is associated with better outcomes as compared to delaying therapy, and this was attributed to a disease modifying effect (as opposed to a symptomatic effect). Whether this is a class effect of MAO-B inhibitors is not known. However, selegiline is metabolized to amphetamine derivatives which have been demonstrated to neutralize neuroprotective effects in various preclinical studies. In a clinical study of the dopamine agonist pramipexole in patients with early IPD, no benefit of earlier initiation over delayed initiation was observed.

**COMT Inhibitors**

Two COMT inhibitors, entacapone and tolcapone, have been developed to extend the effects of l-dopa and are indicated for managing wearing off. Both reduce the peripheral conversion of l-dopa to dopamine, thus enhancing central l-dopa bioavailability. Consequently, in the absence of l-dopa, they have no effect on IPD symptoms. For patients with wearing off, these agents can decrease off-time significantly by increasing the l-dopa area under the curve by approximately 35%. COMT inhibition is considered more effective than controlled-release carbidopa/l-dopa in providing consistent extension of l-dopa effect. A triple-combination product of carbidopa/l-dopa/entacapone offers convenience for some patients (i.e., fewer tablets to administer).

Tolcapone inhibits both peripheral and central COMT. Its use is limited by reports of fatal hepatotoxicity, such that strict monitoring of hepatic function, especially during the first 6 months of therapy, is required. Because of the hepatotoxicity risk, tolcapone is reserved for patients with fluctuations that are not responding to other therapies.

Entacapone has a shorter half-life than tolcapone, and 200 mg needs to be given with each dose of carbidopa/l-dopa up to a maximum of 8 times per day. In clinical trials, both tolcapone and entacapone increased total daily on time by about 1 to 2 hours. Dopaminergic adverse effects may occur and generally are manageable by reduction of the carbidopa/l-dopa dosage. With both agents, brownish-orange urinary discoloration may occur. Also, delayed onset of diarrhea (weeks to months later) can occur in up to 5% of patients. Unlike tolcapone, entacapone is not associated with hepatotoxicity and, if an adjunctive agent is needed for managing motor fluctuations, entacapone is considered one of the first choices.

**Dopamine Agonists**

Dopamine agonists fall into two pharmacologic subtypes: ergot-derived agonists ( bromocriptine and the nonergot agonists ( pramipexole, ropinirole). The nonergot dopamine agonists are safer than the ergot-derived agonists and are useful as monotherapy in mild-moderate IPD, and also as adjuncts to l-dopa therapy in patients with motor fluctuations. The dopamine agonists reduce the frequency of off periods and may allow reductions in l-dopa dosage.

Investigations comparing initial monotherapy with either l-dopa or a dopamine agonist in patients with IPD have revealed a significantly reduced risk of developing motor complications associated with dopamine agonists than with l-dopa. Younger patients are more likely to develop motor complications; consequently, dopamine agonists are preferred over l-dopa. Older patients are more likely to experience intolerable side effects (e.g., hallucinations, orthostatic hypotension) from the dopamine agonists; consequently, carbidopa/l-dopa is preferred, particularly if cognitive problems or dementia is present. In terms of disease-modifying effects, the clinical data with dopamine agonists are inconclusive.

Common adverse effects of dopamine agonists include nausea, confusion, hallucinations, light-headedness, lower-extremity edema, postural hypotension, sedation, and vivid dreaming. Less common but serious adverse effects include compulsive behaviors (e.g., pathologic gambling or shopping, hypersexuality), psychosis, and sleep attacks (sudden, unexpected episodes of sleep). Hallucinations and delusion can be managed using a stepwise approach (Table 68–4) that often involves the use of an atypical antipsychotic medication, such as clozapine or quetiapine. The addition of a dopamine agonist to l-dopa therapy also can increase the frequency and severity of l-dopa induced dyskinesias, especially in patients with preexisting dyskinesias.
Stepwise Approach to Management of Drug-Induced Neurologic Disorders

1. General measures such as evaluating for electrolyte disturbance (especially hyperkalemia or hyponatremia), hypoxemia, or infection (especially encephalitis, sepsis, or urinary tract infection).

2. Simplify the antiparkinsonian regimen as much as possible by discontinuing or reducing the dosage of medications with the highest risk-to-benefit ratio first.
   a. Discontinue anticholinergics, including other nonparkinsonian medications with anticholinergic activity such as antihistamines or tricyclic antidepressants.
   b. Taper and discontinue amantadine.
   c. Discontinue monoamine oxidase-B inhibitor.
   d. Taper and discontinue dopamine agonist.
   e. Consider reduction of l-dopa (especially evening doses) and discontinuation of catechol-O-methyltransferase inhibitors.

3. Consider atypical antipsychotic medication if disruptive hallucinosis or psychosis persists.
   a. Quetiapine 12.5–25 mg at bedtime; gradually increase by 25 mg each week if necessary, until hallucinosis or psychosis improved or
   b. Olanzapine 12.5–50 mg at bedtime; gradually increase by 25 mg each week if necessary until hallucinosis or psychosis improved (requires frequent monitoring for leukopenia).
   c. Discontinue monoamine oxidase-B inhibitor.
   d. Taper and discontinue amantadine.
   e. Consider reduction of l-dopa (especially evening doses) and discontinuation of catechol-O-methyltransferase inhibitors.

4. If dosage reduction or medication discontinuation is either infeasible or undesirable, go to step 5.

Initiation of a dopaminergic agonist is best performed by slow titration to minimize side effects. Pramipexole is initiated at a dose of 0.125 mg 3 times a day and increased every 5 to 7 days, as tolerated, to a maximum of 1.5 mg 3 times a day. An extended-release pramipexole formulation is also available for once-daily administration. Immediate-release ropinirole is initiated at 0.25 mg 3 times a day and increased by 0.25 mg 3 times a day on a weekly basis to a maximum of 24 mg/day. A controlled-release ropinirole formulation for once-daily administration is available.

Pramipexole is renally excreted with an 8- to 12-hour half-life. The initial dosage must be adjusted in renal insufficiency (0.125 mg twice daily for creatinine clearances of 35 to 59 mL/min [0.58 to 0.99 mL/s], 0.125 mg once daily for creatinine clearances of 15 to 35 mL/min [0.25 to 0.57 mL/s]). Ropinirole has a 6-hour half-life and is metabolized by CYP1A2. Potent inhibitors (e.g., fluoroquinolone antibiotics) and inducers (e.g., cigarette smoking) of this enzyme likely will lead to alterations in ropinirole clearance.

Apomorphine is an injectable nonergot dopamine agonist. It is an aporphine alkaloid originally derived from morphine but lacks narcotic properties. Because of extensive hepatic first-pass metabolism, apomorphine is not suitable for oral administration and is administered subcutaneously. In some countries, apomorphine is also available for continuous subcutaneous infusion with minipumps. Apomorphine should not be injected intravenously. For patients with advanced IPD who are experiencing intermittent off episodes despite optimized therapy, administration of subcutaneous apomorphine effectively triggers an “on” response within 20 minutes. The effective dose ranges from 2 to 6 mg per injection, with most patients requiring approximately 0.06 mg/kg. Sites of injection (abdomen, upper arm, and upper thigh) should be rotated to avoid development of subcutaneous nodules. The metabolic pathway of apomorphine remains unknown. Apomorphine elimination half-life is approximately 40 minutes, and the duration of benefit can be up to 100 minutes. Nausea and vomiting are common side effects, and prior to the initiation of apomorphine, patients should be premedicated with the antiemetic trimethobenzamide. Other side effects include dizziness, hallucinations, injection-site irritation, orthostatic hypotension, somnolence, and yawning. As a consequence of reports of severe hypotension and syncope, apomorphine is contraindicated with drugs in the serotonin (5HT2A)-receptor blocker class, including dolasetron, granisetron, and ondansetron.

**SURGICAL THERAPY**

Currently, surgery should be considered as an adjunct to pharmacotherapy when patients are experiencing frequent motor fluctuations or disabling dyskinesia or tremor despite an optimized medical regimen. There are several patient-selection criteria for surgery, including a diagnosis of l-dopa–responsive IPD. Anatomic targets include the thalamus, GPi, and the subthalamic nucleus. Bilateral, chronic, high-frequency electrical stimulation of a target site, also known as deep-brain stimulation (DBS), is the preferred surgical modality.

In DBS surgery, a battery-powered neurostimulator (pacemaker-like device) is implanted subcutaneously below the clavicle and provides constant electrical stimulation, via electrode wires, to the targeted brain structure. Thalamic DBS is very effective for suppressing tremor (specifically arm tremor), but it does not significantly improve the other parkinsonian features (bradykinesia, rigidity, motor fluctuations, or dyskinesias). Although debatable, subthalamic nucleus DBS is favored over GPi DBS because it is considered more effective. Subthalamic nucleus DBS is associated with improvements in tremor, rigidity, bradykinesia, motor fluctuations, and dyskinesia, as well as lowering of antiparkinsonian medications. Problems with gait and postural instability do not improve significantly with DBS (or pharmacotherapy) and remain an unmet need; however, preliminary results for DBS of the pedunculopontine nucleus appear promising.

DBS procedures require routine adjustment of the electrical stimulation parameters (e.g., voltage, frequency, and pulse width) to achieve optimal control while minimizing side effects. The electrical stimulation parameters (or “electrical dosage”) are adjusted via a programmable handheld device to meet each patient’s needs and are performed by physicians as well as other trained individuals, including nurse practitioners and clinical pharmacists.

In recent years, cell-based restorative procedures have appeared promising (implantation of dopamine producing cells such as human fetal mesencephalon tissue or retinal pigmented epithelial cells into the striatum) but have yielded disappointing clinical results. Gene-based therapies are currently under investigation and remain highly experimental.

**PHARMACOECONOMIC CONSIDERATIONS**

Pharmacoeconomic assessments in IPD are important. IPD places a high economic burden on society. Based on an estimated 1 million cases of IPD in the United States, the direct costs associated with IPD are in the range of $4 to $8 billion per year. If indirect costs, such as lost productivity, are included, the economic burden of IPD significantly increases. Patient-specific factors that influence the cost of IPD include age of symptom onset; level of disability; presence of motor complications, falls, and dementia; and need for skilled nursing. For cost-effectiveness, the lowest dose that provides satisfactory symptomatic results should be used and, for patients already on carbidopa-l-dopa, optimization of the l-dopa regimen should be attempted before adding adjunctive agents. As the severity and level of disability increase, so do the costs associated with IPD. Likewise, the costs of treating patients with motor complications are considerably more than the costs of treating patients without motor complications. A similar trend applies for patients with hallucinations and psychosis who incur greater costs associated with nursing home placement. In more advanced
### EVALUATION OF THERAPEUTIC OUTCOMES

Table 68–5 lists the monitoring parameters for Parkinson’s disease therapy. Patient and caregiver satisfaction is an important component of evaluating therapeutic outcomes. Toward this end, establishing appropriate treatment expectations is important and patients and caregivers should be educated that IPD is a neurodegenerative disease that progresses with time, and that some features will respond less well to pharmacotherapy (e.g., freezing, gait and postural instability). Patients and caregivers can participate in treatment by recording medication administration times as well as the duration of on and off times that can be reviewed at each visit. Periodic review of all medications that the patient is taking will respond less well to pharmacotherapy (e.g., D₂-receptor blockers) that can exacerbate idiopathic Parkinson’s disease motor features (e.g., D₂ receptor blockers) or if the presence of an anticholinergic agent is causing cognitive impairment.

### REFERENCES

KEY CONCEPTS

1. It is important, whenever possible, to ask patients if they have pain, to identify the source of pain, and to assess the characteristics of the pain.

2. Patients taking analgesics should be monitored for response and side effects, particularly sedation and constipation associated with the opioids.

3. Oral analgesics are preferred over other dosage forms whenever feasible, but it is important to adjust the route of administration to the needs of the patient.

4. Equianalgesic doses are useful as a guide when converting from one agent to another, but further dose titration usually is required to achieve treatment goals.

5. Doses must be individualized for each patient and administered for an adequate duration of time. Around-the-clock regimens should be considered for acute and chronic pain. As-needed regimens should be used for breakthrough pain or when acute pain displays wide variability and/or has subsided greatly.

6. For chronic pain that has a maladaptive inflammatory and/or neuropathic component, anticonvulsants, topical analgesics, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and opioids should be considered.

7. Whenever possible, a multidisciplinary approach and nonpharmacologic strategies should be used.

8. Placebo therapy should not be used as an attempt to diagnose psychogenic pain.

Although the world is full of suffering, it is also full of the overcoming of it.
Helen Keller

Humans have always known and sought relief from pain. Today, pain’s impact on society still is great, and indeed pain complaints remain a primary reason patients seek medical advice. Regrettably, many healthcare providers do not receive adequate training in this area, and new information is not widely disseminated and/or understood. Clearly, pain management is enhanced when a multidisciplinary approach is applied. Thus, understanding the pathophysiology of pain therapy and maintaining a working knowledge of individual pain regimens are important key factors in addressing pain control.

DEFINITION

The accepted current definition of pain is: “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.” Pain often is so subjective, however, that many clinicians define pain as whatever the patient says it is. The best care is achieved when the patient comes first.

EPIDEMIOLOGY

Data from the National Health and Nutrition Examination Survey indicate that 1 in 4 Americans have suffered pain that lasts for more than 24 hours in the previous month and in those reporting pain, 42% state that it lasted more 1 year. Seventy-six and a half million Americans report they are in chronic pain; this is more than the number of patients with heart disease, cancer, and diabetes combined. The annual cost of pain to U.S. society can be estimated to be in the billions of dollars. In 1 year, an estimated 25 million Americans will experience acute pain due to injury or surgery, and one-third of Americans will experience severe chronic pain at some point in their lives. These numbers are expected to rise, as increasingly more Americans work beyond age 60 years and survive into their 80s. The 106th Congress passed Title VI, Section 1603, of H.R. 3244 which declared a 10-year interval starting January 1, 2001, the “Decade of Pain Control and Research.” Unfortunately, despite much public attention, considerable focused education, and a number of consensus guidelines, pain often remains underestimated and undertreated.

PATHOPHYSIOLOGY

The pathophysiology of pain involves a complex array of neural networks in the brain that are acted on by afferent stimuli to produce the experience we know as pain. In acute pain, this encounter is short lived; but in some situations, the changes may persist, and chronic pain develops.

NOCICEPTIVE PAIN

Nociceptive pain typically is classified as either somatic (arising from skin, bone, joint, muscle, or connective tissue) or visceral
(arising from internal organs such as the large intestine or pancreas). Whereas somatic pain often presents as throbbing and well localized, visceral pain can manifest as pain feeling as if it is coming from other structures (referred) or as a more localized phenomenon. We can think of nociception in terms of stimulation, transmission, perception, and modulation.

**Stimulation**
The first step leading to the sensation of pain is stimulation of free nerve endings known as nociceptors. These receptors are found in both somatic and visceral structures. They distinguish between noxious and innocuous stimuli, and they are activated and sensitized by mechanical, thermal, and chemical impulses. The underlying mechanism of these noxious stimuli (which in and of themselves may sensitize/stimulate the receptor) may be the release of bradykinins, hydrogen and potassium ions, prostaglandins, histamine, interleukins, tumor necrosis factor alfa, serotonin, and substance P (among others) that sensitize and/or activate the nociceptors. Receptor activation leads to action potentials that are transmitted along afferent nerve fibers to the spinal cord (Fig. 69–1).

**Transmission**
Nociceptive transmission takes place in Aδ and C-afferent nerve fibers. Stimulation of large-diameter, sparsely myelinated Aδ fibers evokes sharp, well-localized pain, whereas stimulation of unmyelinated, small-diameter C fibers produces dull, aching, poorly localized pain.

These afferent, nociceptive pain fibers synapse in various layers (laminae) of the spinal cord’s dorsal horn, releasing a variety of neurotransmitters, including glutamate, substance P, and aspartate. The complex array of events that influence pain can be explained in part by the interactions between neuroreceptors and neurotransmitters that take place in this synapse. For example, by stimulating sensory myelinated fibers that intraconnect in the dorsal horn with pain fibers, nonnoxious stimuli can have an inhibitory effect on pain transmission (Fig. 69–1). Functionally, the importance of the interplay between these different fibers and various neurotransmitters and neuroreceptors is evident in the analgesic response produced by topical irritants or transcutaneous electrical nerve stimulation. These pain-initiated processes reach the brain through a complex array of a number of ascending spinal cord pathways, which include the spinothalamic tract. Information other than pain is also carried along these pathways. Thus, pain is influenced by many factors supplemental to nociception and precludes simple schematic representation. It is postulated that the thalamus acts as a relay station, as these pathways ascend and pass the impulses to central structures where pain can be processed further.

**Pain Perception**
At this point in transmission, pain is thought to become a conscious experience that takes place in higher cortical structures. The brain may accommodate only a limited number of pain signals, and cognitive and behavioral functions can modify pain. Relaxation, distraction, meditation, and guided mental imagery may decrease pain by limiting the number of processed pain signals. In contrast, a change in our neurobiochemical makeup that results in states such as depression or anxiety may worsen pain.

**Modulation**
The body modulates pain through a number of complex processes. One, known as the endogenous opiate system, consists of neurotransmitters (e.g., enkephalins, dynorphins, and β-endorphins) and receptors (e.g., μ, δ, and κ) that are found throughout the central nervous system (CNS). Like exogenous opioids, endogenous opioids bind to opioid receptor sites and modulate the transmission of pain impulses. Other receptor types also can influence this system. Blockade of N-methyl-D-aspartate (NMDA) receptors, found in the dorsal horn, may increase the μ-receptors’ responsiveness to opioids.

The CNS also contains a highly organized descending system for control of pain transmission. This system can inhibit synaptic pain transmission at the dorsal horn and originates in the brain. Important neurotransmitters here include endogenous opioids, serotonin, norepinephrine, and γ-aminobutyric acid (GABA).

**Adaptive Inflammation**
Inflammatory pain can be thought of as the body’s shifting from preventing tissue damage to the promotion of healing (e.g., surgical wounds, traumatic injury). As a result of the inflammatory process, the pain threshold is reduced and the injured area becomes more sensitive to pain. This process decreases our contact with and movement of the injured area, thus promoting the progression of healing. When this course of action outlives its functionality or when it is caused by diseases such as arthritis, it can move from an acute to a chronic problem (maladaptive inflammation). According to McPherson: “In response to tissue damage and inflammation, a significant alteration occurs in the chemical composition and properties of the neurons that innervate the inflamed tissues. These alterations reflect the nature and levels of the different proteins expressed by the sensory neurons. Altered production of these proteins may modify the phenotypes of the neurons, changing their transduction and transmission properties. Inflammatory pain is also associated with an increase in the excitability or responsiveness of neurons within the CNS, referred to as central sensitization. This phenomenon, like peripheral sensitization, is a major cause of hypersensitivity to pain after injury.”
NEUROPATHIC AND FUNCTIONAL PAIN

Neuropathic and functional pain is distinctly different from nociceptive pain in that it becomes disengaged from noxious stimuli or healing and often is described in terms of chronic pain. Neuropathic pain is a result of nerve damage, whereas functional pain can be thought of as abnormal operation of the nervous system. A number of neuropathic pain syndromes (e.g., postherpetic neuralgia, diabetic neuropathy) and functional pain syndromes (e.g., fibromyalgia, irritable bowel syndrome, sympathetic induced pain, tension-type headaches, and some noncardiac chest pain) exist. They often are underrecognized and difficult to treat. In addition, the pain reported often is not evident by examining physical findings.

The mechanism responsible for neuropathic and functional pain may be the nervous system’s endogenous dynamic nature. Nerve damage or certain disease states may evoke changes seen in inflammatory pain, ectopic excitability, enhanced sensory transmission, nerve structure reorganization, and loss of modulatory pain inhibition. Pain circuits rewire themselves both anatomically and biochemically. This produces a mismatch between pain stimulation and inhibition, and a potential progressive increase in the discharge of dorsal horn neurons.

Clinically, patients present with episodic or continuous pain transmission (often described as burning, tingling, shock like, or shooting), exaggerated painful response to normally noxious stimuli (hyperalgesia), and/or painful response to normally nonnocuous stimuli (allodynia). This change over time may help to explain why this type of pain often manifests long after the actual nerve-related injury or when no actual injury is identified.

CLASSIFICATION OF PAIN

It is helpful in understanding pain to subdivide the presenting symptoms into acute pain, chronic pain, and cancer pain.

ACUTE PAIN

Acute pain can be a useful physiologic process, warning individuals of disease states and potentially harmful situations. Unfortunately, severe, unremitting, undertreated acute pain, when it outlives its biologic usefulness, can produce many deleterious effects. Aside from unnecessary suffering, untreated and undertreated acute pain has also been shown to increase one’s risk for the development of chronic pain syndromes. Acute pain is usually nociceptive in nature with common causes, including surgery, acute illness, trauma, labor, and medical procedures.

CHRONIC PAIN

Under normal conditions, acute pain subsides quickly as the healing process decreases the pain-producing stimuli; however, in some instances, pain persists for months to years, leading to a chronic pain state with features quite different from those of acute pain (Table 69–1). This type of pain can be nociceptive, neuropathic/functional, or mixed. Chronic pain can be classified as either being associated with cancer (cancer pain) or from noncancer etiologies (chronic noncancer pain). Chronic pain may result in changes to the receptors and nerve fibers in the nervous system, often making treatment even more difficult.

CANCER PAIN

Pain associated with potentially life-threatening conditions is often called malignant pain or simply cancer pain. This type of pain includes both chronic and acute components and often has multiple etiologies. It is pain caused by the disease itself (e.g., tumor invasion, organ obstruction), treatment (e.g., chemotherapy, radiation, surgical incisions), or diagnostic procedures (e.g., biopsy).

CLINICAL PRESENTATION

A patient-oriented approach is essential, and evaluation methods should not differ from those used in other medical conditions. Therefore, a comprehensive history and physical examination are imperative to evaluate underlying diseases and possible other contributing factors. This includes asking if the patient has pain and identifying the source of pain when possible, however, the absence of a discreet etiology should not preclude pain treatment. A baseline characterization of pain can be obtained by assessing characteristics outlined in Table 69–2.

Numerous validated scoring tools exist (e.g., numeric rating scale, visual analog scale, etc.), however the tools need to be appropriate for the type of pain being evaluated, and can be inadequate if not used consistently, or used without clinical judgment. Proper patient assessment must include an evaluation of pain management. Pain intensity, pain relief, and medication side effects (e.g., opioid-induced sedation or constipation) must be assessed and reassessed on a regular basis. The timing and regularity of this assessment will depend on the type of pain and the medications administered. Postoperative pain and acute exacerbation of cancer pain may need to be assessed hourly, whereas chronic noncancer pain may require only daily or less frequent assessment. Pain intensity assessment is vital in acute pain, whereas functionality becomes more of an issue in chronic pain. Quality of life must be assessed on a regular basis in all patients. Many advocate using the four “A”s (analgesia, activity, aberrant drug behavior, and adverse effects) as key assessment measures for any patient with chronic pain.

Data from Twycross and Berry et al.
It is important to note that often objective signs are lacking for pain evaluation. Acute pain may result in increased sympathetic tone (e.g., hypertension, tachycardia, tachypnea); however, this response is usually diminished as acute pain progresses to chronic pain. The clinician must rely on the patient’s description of their pain.24

**CLINICAL PRESENTATION OF PAIN**

**Acute**

**General**

- Obvious distress (e.g., trauma), infants may present with changes in feeding habits, increased fussiness. Those with dementia may exhibit changes in eating habits, increased agitation, calling out. Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear in particular, are noted to lower this threshold, whereas rest, mood elevation, sympathy, diversion, and understanding raise the pain threshold.

**Symptoms**

- Can be described as sharp, dull, shock like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these occur in a timely relationship with an obvious noxious stimuli).

**Signs**

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor, but these signs are not diagnostic.

- In some cases there are no obvious signs.

- Comorbid conditions usually not present.

- Outcome of treatment generally predictable.

**Laboratory Tests**

- Pain is always subjective.

- There are no specific laboratory tests for pain.

- Pain is best diagnosed based on patient description and history.

**Chronic**

**General**

- Can appear to have no noticeable suffering. Attention also must be given to mental/emotional factors that alter the pain threshold. Anxiety, depression, fatigue, anger, and fear in particular, are noted to lower this threshold; whereas rest, mood elevation, sympathy, diversion, and understanding raise the pain threshold.

**Symptoms**

- Can be described as sharp, dull, shock-like, tingling, shooting, radiating, fluctuating in intensity, and varying in location (these often occur without a timely relationship with an obvious noxious stimuli).

- Over time, the pain stimulus may cause symptoms that completely change (e.g., sharp to dull, obvious to vague).

**Signs**

- Hypertension, tachycardia, diaphoresis, mydriasis, and pallor are seldom present.

- In most cases there are no obvious signs.

- Comorbid conditions often present (e.g., insomnia, depression, anxiety).

- Outcome of treatment often unpredictable.

**Laboratory Tests**

- Pain is always subjective.

---

**TREATMENT**

**NONPHARMACOLOGIC THERAPY**

Various nonpharmacologic therapies have been found to be beneficial in the management of acute and chronic pain, including physical manipulation, application of heat or cold, massage, and exercise.25

Transcutaneous electrical nerve stimulation (TENS) has been used in managing both acute and chronic pain (e.g., surgical, traumatic, neuropathy, and musculoskeletal pain).3 However, published evidence regarding long-term benefit is limited. As a result, routine use has not gained widespread acceptance.

Even though the cognitive, behavioral, and social aspects of pain are well established, psychological interventions for the treatment of acute pain are not used widely. Simple interventions (e.g., education or introductory information about sensations to expect after certain procedures) reduce patient distress and greatly reduce postprocedure suffering.26 Other successful psychological techniques, including relaxation training, imagery, and hypnosis, have proven effective in the management of postprocedure pain and in cancer-related pain.26,27 Moderate evidence demonstrates that cognitive behavioral therapy and biofeedback also may be useful nonpharmacologic tools in managing chronic pain.28

**PHARMACOLOGIC TREATMENT**

Many consider pharmacologic treatment to be the cornerstone of pain management.

**Nonopioid Agents**

Analgesia should be initiated with the most effective analgesic agent having the fewest side effects. Acetaminophen, acetylsalicylic acid (aspirin), and nonsteroidal antiinflammatory drugs (NSAIDs) often are preferred over opiates in the treatment of mild-to-moderate pain (Table 69–3). These drugs (with the exception of acetaminophen) prevent formation of prostaglandins produced in response to noxious stimuli, thereby decreasing the number of pain impulses received by the CNS.24 NSAIDs may be particularly useful in the management of cancer-related bone pain.27 Studies comparing the efficacy of these agents have been inconsistent. Therefore, the choice of a particular agent often depends on availability, cost, pharmacokinetics, pharmacologic characteristics, and the side-effect profile. Because of the large interpatient variability in response to individual NSAIDs, it is considered rational therapy to switch to another member of this class if there is inadequate response after a sufficient therapeutic trial of any single agent.24 The duration of a sufficient trial has not been well defined; however, typically, a NSAID should be continued for a minimum of 1 month prior to evaluating the need to switch agents.
The classification of these agents, their equianalgesic doses, relative histamine-releasing characteristics, pharmacokinetics, and dosing guidelines are outlined in Tables 69–4 and 69–5. Opiate choice should be based on patient acceptance; analgesic effectiveness; and pharmacokinetic, pharmacodynamic, and side-effect profiles (Tables 69–4 and 69–5).

The pharmacologic activity of opioids depends on their affinity for opiate receptors. Therapeutic activities and side effects range from those exhibited by the opiate agonists (e.g., morphine) to those seen with the opiate antagonists (e.g., naloxone). Partial

### Opioid Agents

Opioids are often the next logical step in the management of acute pain and cancer-related chronic pain. They also may be an effective treatment option in the management of chronic noncancer pain; however, this continues to be somewhat controversial. Many times a trial of opioids is warranted, but such a trial should not be done without a complete assessment of the pain complaint, including an assessment of the patient’s functionality and risk factors for opioid misuse and abuse.
Neurologic Disorders

**SECTION 6**

Patients in severe pain may receive high doses of opioids with no unwanted side effects, but as the pain subsides, patients may not tolerate even very low doses. Frequently, when opioids are administered, pain is not eliminated, but its unpleasantness is decreased. Patients report that although their pain is still present, it no longer bothers them.

Opioids share related pharmacologic attributes and exert a profound effect on the CNS and gastrointestinal tract. Mood changes, sedation, nausea, vomiting, decreased gastrointestinal motility, constipation, respiratory depression, dependence, and tolerance are evident in varying degrees with all agents. Tolerance to side effects (except to constipation) often develops over time. Some differences exist between the opioids in regards to incidence of side effects. Consideration of these differences assists in selection

(continued)
of the most appropriate agent. The route of administration depends on individual patient needs. In patients who have oral access, the oral route is preferred. However, the onset of analgesic effects for oral medications is approximately 45 minutes, and the peak effect usually occurs 1 to 2 hours after administration. This delay must be a consideration when immediate relief is needed in the management of acute pain. Therefore, in some scenarios, such as acute severe pain (i.e., pain crisis) or when the patient is unable to take oral medications, alternative routes of therapy (e.g., intravenous) may be preferred. The relative potency, defined by the equianalgesic dose, of opioids differs greatly (Table 69–4). Equianalgesic dose tables are often based on single-dose studies without regard for patient variability and should be used only as a guide. True opioid allergies are rare, but Table 69–4 also can be used when treating a patient who is allergic to opiates. Most reactions to opioids, such as itching or rash, are due to the associated histamine release from cutaneous mast cells, not a true allergic or immunoglobulin-E (IgE) or T-cell response. Due to the associated histamine release from cutaneous mast cells, opioids may precipitate withdrawal in opioid-dependent patients. When precipitating withdrawal in opioid-dependent patients, transdermal delivery systems (5, 10, 20 micrograms/hour) available for every 7 day administration may be appropriate. As-needed schedules also may be useful in patients who present with pain that is intermittent or sporadic in nature (Fig. 69–2). When opioids are used in the management of persistent chronic pain, around-the-clock administration schedules should be utilized. As-needed schedules often produce wide swings in analgesic plasma concentrations that create wide swings in pain and sedation. This may initiate a vicious cycle where increasing amounts of pain medications are needed for relief. As the painful state subsides and the need for medication decreases, as-needed schedules may be appropriate. As-needed schedules also may be useful in patients who present with pain that is intermittent or sporadic in nature. Continuous intravenous and subcutaneous methods of opioid infusion are effective for some postoperative pain, but the probability of unwanted side effects is high, and this technique should be reserved for opioid tolerant patients. An alternative method is patient-controlled analgesia (PCA). With this technique, patients can self-administer a preset dose of an intravenous opioid via a pump electronically interfaced with a timing device. Compared with traditional as-needed opioid dosing, PCA yields better pain control, improved patient satisfaction, and relatively few differences in side effects.

Administration of opiates directly into the CNS (e.g., epidural and intrathecal/subarachnoid routes) has shown considerable promise in the control of acute, chronic noncancer, and cancer pain (Table 69–7), and is common in both large and small institutions throughout the United States. Because of reports of respiratory depression, pruritus, nausea, vomiting, urinary retention, and hypotension, these methods of analgesia require careful monitoring and are best used by experienced practitioners.

Continuous intravenous and subcutaneous methods of opioid infusion are effective for some postoperative pain, but the probability of unwanted side effects is high, and this technique should be reserved for opioid tolerant patients. An alternative method is patient-controlled analgesia (PCA). With this technique, patients can self-administer a preset dose of an intravenous opioid via a pump electronically interfaced with a timing device. Compared with traditional as-needed opioid dosing, PCA yields better pain control, improved patient satisfaction, and relatively few differences in side effects.

Administration of opiates directly into the CNS (e.g., epidural and intrathecal/subarachnoid routes) has shown considerable promise in the control of acute, chronic noncancer, and cancer pain (Table 69–7), and is common in both large and small institutions throughout the United States. Because of reports of respiratory depression, pruritus, nausea, vomiting, urinary retention, and hypotension, these methods of analgesia require careful monitoring and are best used by experienced practitioners.
Respiratory depression is of concern and can occur within minutes with intrathecal fentanyl or manifest as late as 19 hours after a single dose of intrathecal morphine. Guidelines mandate respiratory monitoring for at least 24 hours after a single dose of intrathecal or epidural morphine. Naloxone is used to antagonize this effect. Analgesia and side effects are evident at lower doses when opioids are administered intrathecally instead of epidurally. Intrathecally, single morphine doses of 0.1 to 0.3 mg are common, whereas epidurally, doses of 1 to 6 mg are the norm. These intrathecal and epidural opioids often are administered as a continuous-infusion and/or on a patient-controlled basis. When given simultaneously with intrathecal or epidural local anesthetics such as bupivacaine, they have been proven safe and effective. All agents administered directly into the CNS should be preservative free.

Tolerance, Dependence, Addiction, and Pseudoaddiction A barrier that consistently causes clinicians to misjudge and mistreat pain is the misunderstanding of opioid tolerance, physical dependence, addiction, and pseudoaddiction. Tolerance is the reduction of drug effect over time as a result of exposure to the drug. It develops at different rates and with great patient variability. However, with stable disease, opioid use often stabilizes, and tolerance does not lead

Data from American Pain Society and Gatien and Alk.25

Morphine-induced respiratory depression can be reversed by pure opioid antagonists, such as naloxone.26 In patients with underlying pulmonary dysfunction, caution must be used as these patients are already using compensatory breathing mechanisms and are at risk for further respiratory compromise.26 Caution is also urged when combining opiate analgesics with alcohol or other CNS depressants because this combination is potentially harmful and possibly lethal.27

Therapeutic doses of morphine have minimal effects on blood pressure, cardiac rate, or cardiac rhythm when patients are supine; however, morphine does produce venous and arteriolar vessel dilation, and orthostatic hypotension may result. Hypovolemic patients are more susceptible to morphine-induced cardiovascular changes (e.g., decreases in blood pressure).27 Because morphine prompts a decrease in myocardial oxygen demand in ischemic cardiac patients,28 it is often considered the drug of choice when using opioids to treat pain associated with myocardial infarction.

Morphine decreases the propulsive contractions of the gastrointestinal tract and reduces biliary and pancreatic secretions, resulting in constipation. Morphine-induced spasms of the sphincter of Oddi have been observed.29 However, the clinical significance of such an occurrence is unclear. Urinary retention is another potential side effect of morphine; tolerance develops to this effect over time.27 Morphine-induced histamine release often manifests as pruritus, and although not seen often, it may exacerbate bronchospasm in patients with a history of asthma.28 Therapeutic doses of morphine are not contraindicated in head injury, but drug-induced respiratory depression can increase intracranial pressure. Thus, caution is advised in head trauma patients who are not ventilated because morphine may exaggerate this pressure29 and cloud the neurologic examination results.

Morphine is metabolized to two major metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).30 M6G contributes to analgesia, whereas M3G may contribute to side effects.27 The metabolites are renally cleared and can accumulate in patients with renal impairment, contributing to greater side effects.27 Morphine also affects the hypothalamus inhibiting the release of gonadotropin-releasing hormone, thus decreasing plasma testosterone and cortisol.30 Although the clinical meaning has not clearly been elucidated, morphine and other opioids also appear to be immunosuppressive.30

Hydromorphone is more potent, has better oral absorption characteristics, and is more soluble than morphine, but its overall pharmacologic profile parallels that of morphine. Some clinicians believe hydromorphone is associated with fewer side effects, especially pruritus, compared with other opioids. However, the research is limited and does not conclusively demonstrate a difference in side effects between morphine and hydromorphone. Oxydormorphine can be administered orally, rectally, and by injection. Although extended-release and immediate-release oral products have become available, making oxymorphine useful in chronic and acute pain, it offers no pharmacologic advantage over morphine. Levorphanol has an extended half-life, but its overall therapeutic effects are similar to the other agents in this class.

Codeine is a commonly used opiate in the treatment of mild-to-moderate pain. It often is combined with other analgesic products (e.g., acetaminophen). Unfortunately, it has the same propensity to produce side effects as morphine. Hydrocodone is another commonly prescribed opiate and is available for pain only in combination products with other analgesic agents (e.g., acetaminophen, ibuprofen). Its pharmacologic properties are similar to those of morphine. Oxycodeone is a useful oral analgesic for moderate-to-severe pain. This is especially true when the product is used in combination with nonopioids. Although oxycodeone shares basic morphine characteristics, the availability of an immediate-release and controlled-release oral dosage form also makes it very useful in persistent pain as well as acute pain.
**Meperidine and Congeners (Phenylpiperidines)** The prototype phenylpiperidine, meperidine, has a pharmacologic profile comparable with that of morphine; however, it is not as potent and has a shorter analgesic duration. Meperidine offers no analgesic advantage over morphine, has greater toxicity (CNS hyperirritability caused by its renally eliminated metabolite normeperidine), and should be limited in use. In particular, avoid long-term usage, and use in patients at greatest risk for toxicity (e.g., elderly patients and those with renal dysfunction).

Fentanyl is a synthetic opioid structurally related to meperidine that is used often in anesthesiology as an adjunct to general anesthesia. This agent is more potent and faster acting than meperidine (Table 69–4). It can be administered parenterally, transmucosally, and transdermally.

**Methadone and Congeners** Methadone has gained considerable popularity because of its oral efficacy, extended duration of action, and low cost. Although methadone is effective in acute pain, it has gained particular prominence in treating cancer pain and has increasingly been used in the management of chronic noncancer pain. This despite the fact that, with repeated doses, the analgesic duration of action is prolonged, it has an unpredictable half-life, it can cause excessive sedation, and it is difficult to titrate. Properties unique to methadone, compared with other opioids, include the d-isomer’s ability to antagonize NMDA receptors, agonist effects at κ- and δ-opioid receptors, and blockade of serotonin and norepinephrine reuptake. These properties may prove useful in the treatment of neuropathic and chronic pain or in patients with a maladaptive inflammatory component to their pain. However, few trials have thoroughly evaluated methadone’s risks versus benefits. Epidemiologic studies suggest a growing number of methadone-related deaths, and cardiac arrhythmias have been associated with methadone, particularly at higher doses or when used concurrently with other agents that prolong QTc intervals. The equianalgesic dose of methadone may decrease with higher doses of the previous opioid, complicating conversions from other opioids to methadone.

**CLINICAL CONTROVERSY**

Some clinicians believe that methadone should be tried before other opioids in many chronic pain conditions where an opioid is warranted because they believe that neuropathic pain is often a component. Other clinicians believe that sustained-released morphine or oxycodone are better first choices.

Propoxyphene usually is used in combination with acetaminophen for treatment of mild to moderate pain. Propoxyphene is metabolized to norpropoxyphene, a potentially cardio-toxic metabolite. Propoxyphene has been associated with medication injury in the elderly and its use is discouraged in these patients. The U.S. Food and Drug Administration (FDA) has recently required more specific product labeling outlining this agent’s possible risks and is requiring a new safety study to determine its risks versus its benefits.

**Opioid Agonist–Antagonist Derivatives** Analgesic agents that stimulate the analgesic portion of opioid receptors while blocking or having no effect on the toxicity portion would be considered ideal. The agonist–antagonist derivatives were developed with this in mind. This analgesic class produces analgesia and has a ceiling effect on respiratory depression. These agents also have a lower abuse potential than does morphine, but psychotomimetic responses (e.g., hallucinations and dysphoria, as seen with pentazocine), a ceiling analgesic effect, and a propensity to initiate withdrawal in opioid-dependent populations have diminished their widespread clinical use.

**Opioid Antagonists** The pure opioid antagonist naloxone binds competitively to opioid receptors but does not produce an analgesic or opioid side-effect response. Therefore, it is used most often to reverse the toxic effects of agonist- and agonist–antagonist-derived opioids.

**Central Analgesics**

Tramadol and tapentadol are the only centrally acting analgesics currently available in the United States. Tramadol binds to μ-opiate receptors and inhibits norepinephrine and serotonin reuptake. Tapentadol also binds the μ-opiate receptor but inhibits largely norepinephrine reuptake. Tramadol is indicated for the relief of moderate to moderately severe pain, while tapentadol is indicated for moderate to severe acute pain.

Both tramadol and tapentadol have side-effect profiles similar to that of the previously mentioned opioid analogesics (e.g., dizziness, nausea, somnolence, and constipation). Tapentadol is a schedule II controlled substance, while tramadol is not scheduled. Tapentadol has not been systematically evaluated in patients with seizure, and it should be used with caution in seizure patients. Seizure risk may be elevated in patients taking tramadol. Tramadol, may have a place in treating patients with chronic pain, especially neuropathic pain, while tapentadol may be most useful in the management of acute pain.

**Adjuvant Analgesics**

Adjuvant analgesics are pharmacologic agents with individual characteristics that make them useful in the management of pain but that typically are not classified as analgesics. Examples of adjuvant analgesics include antidepressants and anticonvulsants. Chronic pain that has a maladaptive inflammatory (e.g., low back pain) and/or neuropathic component (e.g., diabetic neuropathy) may require such agents (Table 69–8). Anticonvulsants (e.g., gabapentin, which may decrease neuronal excitability), tricyclic antidepressants, serotonin and norepinephrine reuptake inhibitor antidepressants (which block the reuptake of serotonin and norepinephrine, thus enhancing pain inhibition), and topicaly applied local anesthetics (which decrease nerve stimulation) all have been effective in managing chronic pain.

In cancer patients, bone pain can be treated with radiopharmaceuticals. Both strontium-89 and samarium 153Sm lexidronam have been shown to provide pain relief. Although antihistamines, amphetamines, and steroids have been used as adjuvant pain medications, they have demonstrated only limited success as pain relievers.

**Combination Therapy**

The combination of opioid and nonopioid analgesics often results in analgesia superior to that produced by either agent alone. This facilitates the use of lower doses and a more favorable side-effect profile, and, when needed, this approach is encouraged.

**Regional Analgesia**

Regional analgesia with properly administered local anesthetics can provide relief of both acute and chronic pain (Table 69–9). These agents can be positioned by injection (e.g., in joints, in the epidural or intrathecal space, along nerve roots, or in a nerve plexus) or topically. Lidocaine in the form of a patch has proven effective in treating focal neuropathic pain. Regional application of local...
anesthetics relieve pain by blocking nerve impulses. High plasma concentrations can cause signs of CNS excitation and depression, including dizziness, tinnitus, drowsiness, disorientation, muscle twitching, seizures, and respiratory arrest. Cardiovascular effects include myocardial depression, hypotension, decreased cardiac output, heart block, bradycardia, arrhythmias, and cardiac arrest. Disadvantages of such methods include the need for skillful technical application, need for frequent administration, and highly specialized followup procedures.

### SPECIAL CONSIDERATIONS IN ACUTE PAIN

The World Health Organization (WHO) recommends a three-step ladder approach using the simplest dosage schedules and medications with the least amount of potential harm based on pain intensity ratings from mild, to moderate, to severe. An acute pain algorithm outlining how to use these principles is given in Figure 69–2. The importance of reassessment and titration during this process cannot be overemphasized.

### SPECIAL CONSIDERATIONS IN CANCER PAIN

Managing the pain of cancer encompasses both acute and chronic management techniques. Thus, pharmacologic treatment and psychological therapies are best combined with surgical methods, anesthetic procedures, and supportive care measures in a multidisciplinary approach to pain relief. The goal is to provide patients with enough pain amelioration to tolerate diagnostic and therapeutic manipulation and permit the patient to function at a level that will allow freedom of movement and choice.

of the factors given in Table 69–2 also applies to cancer patients. Special attention must be given to continual reassessment of the painful state, adverse effects with medications, and aberrant behaviors. Individualization of therapy is always required. Supportive care, in and outside the hospital, using programs such as hospice, is one of the cancer patient’s greatest allies, not only in coping with pain but also in accepting the disease. The positive effect this has on the patient cannot be overstated. Pharmacologic management is the mainstay of therapy, and a typical progression of analgesic use in oncology patients is outlined in Figure 69–3.

### CLINICAL CONTROVERSY

Many clinicians believe that some chronic painful conditions (e.g., osteoarthritis) should never be treated with opioids; whereas others believe that when other modalities are not effective or seem to pose more of a risk to that particular patient than does conventional therapy (e.g., NSAIDs), then opioids are necessary.
CHAPTER 69

Maximum daily dose:
Algorithm for pain management in oncology patients.

1. Assess the frequency/duration/occurrence/etiology of the pain on a routine basis.
2. If bone pain is present, consideration of an NSAID should be routine.
3. Always dose a medication to its maximum before reverting to the next step, unless pain is totally out of control.
4. If pain is constant or recurring, always dose around-the-clock (ATC).
5. Some authors suggest a lower maximum dose of acetaminophen.

---

**SPECIAL POPULATIONS**

The elderly and the young are at a higher risk for undertreatment because of inability to communicate or rate their pain. It is in these cases that parent or caregiver input becomes paramount to identify changes in behavior which might suggest pain (e.g., fussy, inconsolable, changes in eating patterns, crying out, or agitation). In addition, those living with chronic, debilitating, and life-threatening illnesses need specialized pain control and care that is palliative in nature. Although care must be taken in these populations to ensure that proper individualized treatment plans follow accepted guidelines, the key concepts in pain management as outlined in this chapter are the guiding tenets in maximizing pain control.

---

**PHARMACOECONOMIC CONSIDERATIONS**

The suffering component of pain cannot be overemphasized. Swift relief from acute and cancer pain and well-planned treatment regimens in chronic noncancer pain will allow patients to concentrate...
on recovery and regaining control of their lives. Although few well-designed pharmacoeconomic studies have been performed, most pain clinicians believe that this approach minimizes time in the hospital and time away from work while maximizing quality of life.

**EVALUATION OF THERAPEUTIC OUTCOMES**

The key to treating pain effectively is consistent monitoring for effectiveness (pain relief) versus side effects (e.g., sedation) and titrating treatment accordingly. In acute pain, this often must be done several times per day (in the early stages, hourly), whereas in chronic pain this may occur daily or even weekly. The frequency of evaluation also depends on the drug, the administration route, and other therapies being used. When patients cannot be asked about their pain (e.g., coma), monitoring agitation and heart rate is appropriate. Given the subjective nature of pain, the most successful therapies involve not only frequent patient assessment but also a large degree of patient control (as with PCA). With chronic pain, tools such as the Brief Pain Inventory, Initial Pain Assessment Inventory, McGill Pain Questionnaire, or pain drawings may be helpful.

All opioids can cause constipation. The best management of constipation is prevention. Patients should be counseled on the proper intake of fluids and fiber. A stimulating laxative should be added with chronic opioid use. As noted earlier, CNS depressants (e.g., alcohol, benzodiazepines) amplify CNS depression when used with opioid analgesics, and use of these combinations should be discouraged when possible. When the combinations are used, patients should be monitored closely.

**CONCLUSIONS**

Poor training of healthcare practitioners in pain assessment and management, improper patient education, and inadequate communication among healthcare professionals are some of the reasons for inadequate pain relief. The use of an integrated approach, incorporating the expertise of many disciplines, may well be the most overlooked principle of pain pharmacotherapy. It is the responsibility of all healthcare professionals who deal with pain to work together to ensure proper management.

KEY CONCEPTS

1. Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work.

2. A stratified care approach, in which the selection of initial treatment is based on headache-related disability and symptom severity, is the preferred treatment strategy for the migraineur.

3. Strict adherence to maximum daily and weekly doses of antimigraine medications is essential.

4. Preventive therapy should be considered in the setting of recurring migraines that produce significant disability; frequent attacks requiring symptomatic medication more than twice per week; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury.

5. The selection of an agent for migraine prophylaxis should be based on individual patient response, tolerability, convenience of the drug formulation, and comorbid conditions.

6. Each prophylactic medication should be given an adequate therapeutic trial (usually 2–6 months) to judge its efficacy.

7. A general wellness program and avoidance of migraine triggers should be included in the management plan.

8. After an effective abortive agent and dose have been identified, subsequent treatments should begin with that same regimen.

MIGRAINE HEADACHE

EPIDEMIOLOGY

Results of the American Migraine Prevalence and Prevention Study indicate that 17.1% of women and 5.6% of men in the United States experience one or more migraine headaches per year. The prevalence of migraine varies considerably by age and gender, but the epidemiologic profile has remained stable over the past 15 years. Before the age of 12 years, migraine is more common in boys than in girls, but prevalence increases more rapidly in girls after puberty. After age 12, females are two to three times more likely than males to suffer from migraine. Gender differences in migraine prevalence have been linked to menstruation, but these differences persist beyond menopause. Prevalence is highest in both men and women between the ages of 30 and 49 years. The usual age of onset is 12 to 17 years of age for females and 5 to 11 years for males. In the American Migraine Prevalence and Prevention Study, 93% of those with migraine reported some headache-related disability, and 54% were severely disabled or needed bed rest during an attack. A number of neurologic and psychiatric disorders as well as cardiovascular diseases, including stroke, epilepsy, major depression, sleep apnea, and anxiety disorder, show increased comorbidity with migraine. Whether this relationship is causal or representative of a common pathophysiologic mechanism is unknown. The economic burden of migraine is substantial; however, the indirect
ETIOLOGY AND PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of migraine are not completely understood. According to earlier theories, the migraine aura was caused by intracerebral arterial vasodilation followed by reactive extracranial vasoconstriction and associated headache. Although studies of regional blood flow in the brain do not support this vascular hypothesis, the aura phase of migraine is associated with reactive extracranial vasodilation and associated headache. Previous vascular and neural theories of migraine development have merged into a combined theory of neurovascular mechanisms. Activity within the trigeminal system may be regulated by reactive extracranial vasodilation and associated headache. Although the exact pathophysiology of migraine needs further elucidation, new neuroimaging techniques have provided insight into mechanisms. Genetic factors seem to play an important role in susceptibility to migraine attacks. Studies in monozygotic twins suggest approximately 50% heritability of migraine with a multifactorial polygenic basis. Although it is possible for any individual to experience a migraine attack, it is recurrence in the migraineur that is abnormal. Attack occurrence and frequency are governed by CNS sensitivity to migraine-specific triggers or environmental factors. Migraineurs appear to have a lowered threshold of neuronal excitability through the release of serotonin and other excitatory neurotransmitter release in brainstem nuclei that mediate migraine attack initiation. Although the mechanisms of attack initiation are not fully understood, the migraine generator may be related to a defect or dysfunction in the activity of neuronal calcium channels mediating serotonin release and pain signal transmission.

Costs from work-related disability far exceed the direct costs associated with treatment. Costs from work-related disability far exceed the direct costs associated with treatment.

migraine prophylaxis also modulate neurotransmitter systems. These actions and benefits in migraine management are consistent with the current understanding of migraine pathophysiology and neurovascular disorders.

**CLINICAL PRESENTATION**

The migraine attack has been divided into several phases. Premonitory symptoms are experienced by approximately 20% to 60% of migraineurs in the hours or days before the onset of headache. The previously popular terms prodrome and warning symptoms should be avoided because these are often used mistakenly to include aura. Premonitory symptoms vary widely among migraineurs but usually are consistent within an individual. Neurologic symptoms (e.g., phonophobia, photophobia, hyperosmia, and difficulty concentrating) are most common, but psychological (e.g., anxiety, depression, euphoria, irritability, drowsiness, hyperactivity, and restlessness), autonomic (e.g., polyuria, diarrhea, and constipation), and constitutional symptoms (e.g., stiff neck, yawning, thirst, food cravings, and anorexia) also are reported.Associated with nausea, vomiting, and sensitivity to light, sound, and/or movement. Not all symptoms are present at every attack.

In the headache evaluation, diagnostic alarms should be identified. These include: acute onset of the “first” or “worst” headache ever, accelerating pattern of headache following subacute onset, onset of headache after age 50 years, headache associated with systemic illness (e.g., fever, nausea, vomiting, stiff neck, and rash), headache with focal neurologic symptoms or papilledema, and new-onset headache in a patient with cancer or human immunodeficiency virus infection.

**Signs**

A stable pattern, absence of daily headache, positive family history for migraine, normal neurologic examination, presence of food triggers, menstrual association, long-standing history, improvement with sleep, and subacute evolution are all signs of migraine headache. Aura can signal the migraine headache but is not required for diagnosis.

**Laboratory Tests**

In selected circumstances and secondary headache presentation, serum chemistries, urine toxicology profiles, thyroid function tests, lyme studies, and other blood tests such as a complete blood count, antinuclear antibody titer, erythrocyte sedimentation rate, and antiphospholipid antibody titer can be considered.

**Diagnostic Tests**

Perform a general medical and neurologic physical examination. Check for abnormalities: vital signs (fever, hypertension), funduscopy (papilledema, hemorrhage, and exudates), palpation and auscultation of the head and neck (sinus tenderness, hardened or tender temporal arteries, trigger points, temporomandibular joint tenderness, bruits, nuchal rigidity,
The migraine aura, a complex of positive and negative focal neurologic symptoms that precedes or accompanies an attack, is experienced by approximately 31% of migraineurs on some occasions. The aura typically evolves over 5 to 20 minutes and lasts less than 60 minutes. Headache usually occurs within 60 minutes of the end of the aura. Occasionally, aura symptoms begin at the onset of headache or during the attack. The aura is most often visual and frequently affects half the visual field. Visual auras vary in their complexity and can include both positive (scintillations, photopsia, teichopsia, or fortification spectrum) and negative (scotoma, hemianopsia) features. Sensory and motor aura symptoms, such as paresthesias or numbness involving the arms and face, dysphasia or aphasia, weakness, and hemiparesis, also are reported.

Of those with migraine in the United States, 14% experience more than four attacks per month, 63% experience one to four attacks per month, and 23% experience less than one attack per month. Migraine headache can occur at any time of the day or night but occurs most often in the early morning hours on awakening. Pain is usually gradual in onset, peaking in intensity over a period of minutes to hours and lasting between 4 and 72 hours. Pain can occur anywhere in the face or head but most often involves the frontotemporal region. The headache is typically unilateral and throbbing or pulsating in nature; however, pain can be bilateral at onset or become generalized during the course of an attack. Gastrointestinal symptoms almost invariably accompany the headache. During an attack, as many as 90% of migraineurs experience nausea, and emesis occurs in approximately one-third of patients. Other systemic symptoms associated with the headache phase include anorexia, food cravings, constipation, diarrhea, abdominal cramps, nasal stuffiness, blurred vision, diaphoresis, facial pallor, and localized facial, scalp, or periorbital edema. Sensory hyperacuity, manifested as photophobia, phonophobia, or osmophobia, is reported frequently. Because headache pain usually is aggravated by physical activity, most migraineurs seek a dark, quiet room for rest and relief. Impaired concentration, depression, irritability, fatigue, or anxiety often accompany the headache. Once headache pain wanes, patients may experience a resolution phase characterized by feeling tired, exhausted, irritable, or listless. Impaired concentration may continue, as well as scalp tenderness or mood changes. Some patients experience depression and malaise, whereas others can feel unusually refreshed or euphoric. The reader is referred to the IHS classification and recent reviews for descriptions of the classic migraine variants and other migraine subtypes (see also Table 70–1).

Although headaches have many potential causes, most are considered to be primary headache disorders. A comprehensive headache history is the most important element in establishing the clinical diagnosis of migraine. A thorough headache history always should be obtained, and information collected should include age at onset, attack frequency and timing, duration of attacks, precipitating or aggravating factors, ameliorating factors, description of neurologic symptoms, characteristics of the headache pain (quality, intensity, location, and radiation), associated signs and symptoms, treatment history, family and social history, and the impact of headaches on daily life.

Secondary headache can be identified or excluded based on the headache history, as well as the results of general medical and neurologic examinations. Diagnostic and laboratory testing also can be warranted in the setting of suspicious headache features or an abnormal examination. The routine use of neuroimaging (computed tomography or magnetic resonance imaging) generally is not indicated in patients with migraine and a normal neurologic examination, but should be considered in patients with an unexplained abnormal neurologic examination or an atypical headache history.

Because migraine headaches usually begin by the second or third decade of life, headaches beginning after age 50 years suggest an organic etiology such as a mass lesion, cerebrovascular disease, or temporal arteritis. Table 70–2 lists the IHS diagnostic criteria for migraine with and without aura.

### Treatment

#### Migraines

**Desired Outcome**

Clinicians who care for migraineurs must appreciate the impact of this painful and debilitating disorder on the life of the patient, the patient’s family, and the patient’s employer. Treatment strategies must address both immediate and long-term goals. Acute migraine therapies should provide consistent, rapid relief and enable the patient to resume normal activities at home, school, or work. Recurrence of symptoms and treatment-related adverse

**Goals for acute migraine treatment**

| Treat migraine attacks rapidly and consistently without recurrence |
| Restore the patient’s ability to function |
| Minimize the use of backup and rescue medications* |
| Optimize self-care for overall management |
| Be cost-effective in overall management |
| Cause minimal or no adverse effects |

*Rescue medications are defined as medications used at home when other treatments fail that permit the patient to get relief without a visit to the physician’s office or emergency department. Data from Diamond and Cody* and Matzan et al.**

**GENERAL APPROACH TO TREATMENT**

Nonpharmacologic and pharmacologic interventions are available for the management of migraine headache; however, drug therapy remains the mainstay of treatment for most patients. Pharmacotherapeutic management of migraine can be acute (e.g., symptomatic or abortive) or preventive (e.g., prophylactic). When choosing acute or preventive therapies, the clinician should consider the patient’s response to specific medications and their tolerability, as well as coexisting illnesses that can limit treatment choices. Abortive or acute therapies can be migraine-specific (e.g., ergots and triptans) or nonspecific (e.g., analgesics, antiemetics, nonsteroidal antiinflammatory drugs [NSAIDs], and corticosteroids) and are most effective at relieving pain and associated symptoms when administered at the onset of migraine.  

A stratified care approach in which the selection of initial treatment is based on headache-related disability and symptom severity is the preferred treatment strategy for the migraineur.  

Because attack severity varies in individuals, patients may be advised to use nonspecific agents for mild to moderate headache not causing disability while reserving migraine-specific medications for more severe attacks. The absorption and efficacy of orally administered drugs can be compromised by gastric stasis or nausea and vomiting that accompany migraine headaches. Pretreatment with antiemetic agents or the use of nonoral treatments (e.g., suppositories, nasal sprays, or injections) is advisable when nausea and vomiting are severe.  

The frequent or excessive use of acute migraine medications can result in a pattern of increasing headache frequency and drug consumption known as medication-overuse headache (or rebound headache). The syndrome appears to evolve as a self-sustaining headache-medications cycle in which the headache returns as the medication wears off, leading to the consumption of more drug for relief. The headache history often reflects the gradual onset of an atypical daily or near-daily headache with superimposed episodic migraine attacks. Medication overuse is one of the most common causes of chronic daily headache. Agents most commonly implicated in this syndrome include simple and combination analgesics and opiates. Triptans are also implicated but only in men with a high frequency of headaches. Discontinuation of the offending agent leads to a gradual decrease in headache frequency and severity and a return of the original headache characteristics. Although detoxification usually can be accomplished on an outpatient basis, hospitalization can be necessary for the control of refractory rebound headache and other withdrawal symptoms (e.g., nausea, vomiting, asthenia, restlessness, and agitation).  

Regulation of nociceptive systems and renewed responsiveness to therapy usually occur within 2 months following medication withdrawal. Most experts recommend limiting use of acute migraine therapies to 2 or 3 days per week to avoid the development of medication-misuse headache.  

Preventive migraine therapies are administered on a daily basis to reduce the frequency, severity, and duration of attacks and improve responsiveness to symptomatic migraine therapies (Table 70–5).  

Preventive therapy should be considered in the setting of recurring migraines that produce significant disability despite acute therapy; frequent attacks occurring more than twice per week with the risk of developing medication-overuse headache; symptomatic therapies that are ineffective, contraindicated, or produce serious side effects; uncommon migraine variants that cause profound disruption and/or risk of permanent neurologic injury (e.g., hemiplegic migraine, basilar migraine, and migraine with prolonged aura); and patient preference to limit the number of attacks. Preventive therapy also may be administered preemptively or intermittently when headaches recur in a predictable pattern (e.g., exercise-induced migraine or menstrual migraine). The efficacy of the various agents used for migraine prophylaxis appears to be similar, but the quality of published data is limited for many commonly used drugs. Only propranolol, timolol, valproate, and topiramate are currently approved by the U.S. Food and Drug Administration (FDA) for the indication. Thus the selection of an agent typically is based on its side-effect profile and the patient’s comorbid conditions.  

A therapeutic trial of 2 to 6 months is necessary to judge medication efficacy, but some reduction in attack frequency can be evident by the first month of therapy. Drug therapy should be initiated with low doses and gradually increased until a therapeutic effect is achieved or side effects become intolerable. Drug doses for migraine prophylaxis are often lower than those necessary for other indications. Overuse of acute headache medications will interfere with the effects of preventive treatment. Prophylactic treatment usually is continued for at least 3 to 6 months after the frequency and severity of headaches have diminished and then is tapered gradually and discontinued. Many migraineurs experience fewer and less severe attacks for lengthy periods following discontinuation of prophylactic medications or taper to a lower dose. Figures 70–2 and 70–3 identify treatment and management algorithms for migraine headache.  

**NONPHARMACOLOGIC THERAPY**

Nonpharmacologic therapy of acute migraine headache is limited but can include application of ice to the head and periods of rest or sleep, usually in a dark, quiet environment. Preventive management of migraine should begin with the identification and avoidance of factors that consistently provoke migraine attacks in susceptible individuals. Changes in estrogen levels associated with menarche, menstruation, pregnancy, menopause, oral contraceptive use, and other hormone therapies can trigger, intensify, or alleviate migraine. A headache diary
relaxation therapy, biofeedback (often used in combination with relaxation therapy), and cognitive therapy, are preventive treatment options for patients who prefer nondrug therapy or when symptomatic therapies are poorly tolerated, contraindicated, or ineffective. 14, 22

that records the frequency, severity, and duration of attacks can facilitate identification of migraine triggers. 7 Patients also can benefit from adherence to a wellness program that includes regular sleep, exercise, and eating habits, smoking cessation, and limited caffeine intake. Behavioral interventions, such as

CHAPTER 70

Treatment algorithm for migraine headaches.

Analgesics and NSAIDs

Simple analgesics and NSAIDs are effective medications for the management of many migraine attacks. They offer a reasonable first-line choice for treatment of mild to moderate migraine attacks or severe attacks that have been responsive in the past to similar NSAIDs or nonopiate analgesics. Of the NSAIDs, aspirin, ibuprofen, naproxen sodium, tolfenamic acid, and the combination of acetaminophen plus aspirin and caffeine have demonstrated the most consistent evidence of efficacy. Evidence for other NSAIDs is either limited or inconsistent. Acetaminophen alone is not generally recommended for migraine because the scientific support is not optimal. Comparisons with other pharmacotherapeutic classes are limited.

NSAIDs appear to prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of prostaglandin synthesis. Metoclopramide can speed the absorption of analgesics and alleviate migraine-related nausea and vomiting. Suppository analgesic preparations are an option when nausea and vomiting are severe. Acute NSAID therapy is associated with gastrointestinal (e.g., dyspepsia, nausea, vomiting, and diarrhea) and CNS side effects (e.g., somnolence, dizziness). NSAIDs should be used cautiously in patients with previous ulcer disease, renal disease, or hypersensitivity to aspirin.

The over-the-counter combination of acetaminophen, aspirin, and caffeine was approved for the treatment of migraine in the United States because of its proven efficacy in relieving migraine pain and associated symptoms. Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine, propoxyphene). No randomized, placebo-controlled studies support the efficacy of butalbital-containing analgesics or narcotics should be limited because of concerns about overuse, medication-overuse headache, and withdrawal. Midrin, a combination of acetaminophen, isometheptene mucate (a sympathomimetic

CLINICAL CONTROVERSY

Patients are advised to avoid foods and even medications that are identified as migraine triggers. Despite these recommendations, convincing evidence is lacking for many commonly mentioned dietary triggers. Keeping a headache diary can help patients identify risk factors and personal triggers.

PHARMACOLOGIC MANAGEMENT OF ACUTE MIGRAINE

CLINICAL CONTROVERSIES

The availability of many over-the-counter drugs that were formerly prescription medications enables some migraine patients to self-medicate and delay entry into appropriate medical management. Some clinicians feel that over-the-counter products invite patients to take a less effective step-care approach and avoid being treated according to evidence-based guidelines.

Although controversial, some clinicians argue that the efficacy and tolerability of over-the-counter medications for migraine relief are limited because of patient dissatisfaction with the route of administration, the onset of action, the completeness of pain relief, and the length of suffering and prolonged disability.

migraine attacks or severe attacks that have been responsive in the past to similar NSAIDs or nonopiate analgesics. Of the NSAIDs, aspirin, ibuprofen, naproxen sodium, tolfenamic acid, and the combination of acetaminophen plus aspirin and caffeine have demonstrated the most consistent evidence of efficacy. Evidence for other NSAIDs is either limited or inconsistent. Acetaminophen alone is not generally recommended for migraine because the scientific support is not optimal. Comparisons with other pharmacotherapeutic classes are limited.

NSAIDs appear to prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of prostaglandin synthesis. Metoclopramide can speed the absorption of analgesics and alleviate migraine-related nausea and vomiting. Suppository analgesic preparations are an option when nausea and vomiting are severe. Acute NSAID therapy is associated with gastrointestinal (e.g., dyspepsia, nausea, vomiting, and diarrhea) and CNS side effects (e.g., somnolence, dizziness). NSAIDs should be used cautiously in patients with previous ulcer disease, renal disease, or hypersensitivity to aspirin.

The over-the-counter combination of acetaminophen, aspirin, and caffeine was approved for the treatment of migraine in the United States because of its proven efficacy in relieving migraine pain and associated symptoms. Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine, propoxyphene). No randomized, placebo-controlled studies support the efficacy of butalbital-containing analgesics or narcotics should be limited because of concerns about overuse, medication-overuse headache, and withdrawal. Midrin, a combination of acetaminophen, isometheptene mucate (a sympathomimetic

migraine attacks or severe attacks that have been responsive in the past to similar NSAIDs or nonopiate analgesics. Of the NSAIDs, aspirin, ibuprofen, naproxen sodium, tolfenamic acid, and the combination of acetaminophen plus aspirin and caffeine have demonstrated the most consistent evidence of efficacy. Evidence for other NSAIDs is either limited or inconsistent. Acetaminophen alone is not generally recommended for migraine because the scientific support is not optimal. Comparisons with other pharmacotherapeutic classes are limited.

NSAIDs appear to prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of prostaglandin synthesis. Metoclopramide can speed the absorption of analgesics and alleviate migraine-related nausea and vomiting. Suppository analgesic preparations are an option when nausea and vomiting are severe. Acute NSAID therapy is associated with gastrointestinal (e.g., dyspepsia, nausea, vomiting, and diarrhea) and CNS side effects (e.g., somnolence, dizziness). NSAIDs should be used cautiously in patients with previous ulcer disease, renal disease, or hypersensitivity to aspirin.

The over-the-counter combination of acetaminophen, aspirin, and caffeine was approved for the treatment of migraine in the United States because of its proven efficacy in relieving migraine pain and associated symptoms. Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine, propoxyphene). No randomized, placebo-controlled studies support the efficacy of butalbital-containing analgesics or narcotics should be limited because of concerns about overuse, medication-overuse headache, and withdrawal. Midrin, a combination of acetaminophen, isometheptene mucate (a sympathomimetic
amino-1, and dichlorphenazone (a chloral hydrate derivative), has demonstrated modest benefits in placebo-controlled studies and generally is viewed as an alternative for patients with mild to moderate migraine attacks.\textsuperscript{13,17} Although frequent consumption of aspirin or acetaminophen alone can result in medication-overuse headache, combination analgesics appear to pose a greater risk.\textsuperscript{7,16}

### Opiate Analgesics

Narcotic analgesic drugs (e.g., meperidine, butorphanol, oxycodone, and hydromorphone) are effective but generally should be reserved for patients with moderate to severe infrequent headaches in whom conventional therapies are contraindicated or as “rescue medications” after patients have failed to respond to conventional therapies.\textsuperscript{7} Frequent use of narcotic analgesics can lead to the development of dependency and rebound headache.\textsuperscript{26} The intranasal formulation of butorphanol, a synthetically derived opioid agonist-antagonist, is a treatment option but should be reserved for use only as an alternative to frequent office or emergency department visits for injectable migraine therapies. Opioid therapy should be supervised closely.\textsuperscript{16,17}

### Antiemetics

Adjunctive antiemetic therapy is useful for combating the nausea and vomiting that accompany migraine headaches and the medications used to treat attacks (e.g., ergotamine tartrate). A single dose of an antiemetic, such as metoclopramide, chlorpromazine, or prochlorperazine, administered 15 to 30 minutes before ingestion of oral abortive migraine medications is often sufficient. Suppository preparations are available when nausea and vomiting are particularly prominent. Metoclopramide is also useful to reverse gastroparesis and improve absorption from the gastrointestinal tract during severe attacks.\textsuperscript{15,16}

In addition to antiemetic effects, dopamine antagonist drugs also have been used successfully as monotherapy for the treatment of intractable headache (see Table 70–4). Prochlorperazine administered by the intravenous and intramuscular routes and intravenous metoclopramide provided more effective pain relief than placebo. Chlorpromazine also has provided relief of migraine headache when administered parenterally at doses of 12.5 to 37.5 mg. Domperidone has a possible role for preemptive treatment of migraine. The precise mechanism of action for these agents is unknown. The dopamine antagonists offer an alternative to the narcotic analgesics for the treatment of refractory migraine. Drowsiness and dizziness were reported occasionally and extrapyramidal side effects were reported infrequently in migraine trials.\textsuperscript{15,25}

### Miscellaneous Nonspecific Medications

Corticosteroids can be considered as rescue therapy for status migrainous (a severe, continuous migraine that can last up to 1 week).\textsuperscript{7,15} Intravenous or intramuscular dexamethasone at a dose of 10 to 25 mg has also been used as an adjunct to abortive therapy.\textsuperscript{25,27}

Limited studies suggest a role for intranasal lidocaine in the treatment of acute migraine headache.\textsuperscript{15} Intranasal lidocaine, 1 to 4 drops of a 4% solution, provides rapid pain relief within 15 minutes of administration, but headache recurrence is common. Adverse effects generally are limited to local irritation, an unpleasant taste, and numbness of the throat.

---

### TABLE 70–6 Commonly Reported Triggers of Migraine

| Food triggers            |  |
|--------------------------|  |
| Alcohol                  |  |
| Caffeine/caffeine withdrawal |  |
| Chocolate                |  |
| Fermented and pickled foods |  |
| Monosodium glutamate (e.g., in Chinese food, seasoned salt, and instant foods) |  |
| Nitrate-containing foods (e.g., processed meats) |  |
| Saccharin/aspartame (e.g., diet foods or diet sodas) |  |
| Tyramine-containing foods |  |

| Environmental triggers    |  |
|---------------------------|  |
| Glare or flickering lights |  |
| High altitude             |  |
| Loud noises               |  |
| Strong smells and fumes   |  |
| Tobacco smoke             |  |
| Weather changes           |  |

| Behavioral–physiologic triggers |  |
|---------------------------------|  |
| Excess or insufficient sleep    |  |
| Fatigue                         |  |
| Menstruation, menopause         |  |
| Sexual activity                 |  |
| Skipped meals                   |  |
| Strenuous physical activity (e.g., prolonged overexertion) |  |
| Stress or post-stress           |  |

Data from Diamond and Cady,\textsuperscript{14} Buse et al.,\textsuperscript{22} and Kelman.\textsuperscript{24}
Preliminary investigations of intramuscular droperidol have yielded favorable results in the treatment of acute migraine headache. Future studies might establish a more defined role for this agent in migraine management.

**Ergot Alkaloids and Derivatives**

Ergotamine tartrate and dihydroergotamine are useful and can be considered for the treatment of moderate to severe migraine attacks (see Table 70–4). These drugs are nonselective 5-HT<sub>1</sub> receptor agonists that constrict intracranial blood vessels and inhibit the development of neurogenic inflammation in the trigeminovascular system. Central inhibition of the trigeminovascular pathway is also reported as well as agonist activity at dopaminergic receptors. Venous and arterial constriction occur with therapeutic doses, but ergotamine tartrate exerts more potent arterial effects than dihydroergotamine.<sup>1,4,17,26</sup>

Ergotamine tartrate is available for oral, sublingual, and rectal administration. Oral and rectal preparations contain caffeine to enhance absorption and potentiate analgesia. Some patients respond preferentially to rectal dosing.<sup>7,14</sup> Dosage requirements should be titrated strictly to establish an effective but subnauseating dose for future attacks. Ergotamine is most effective when administered early in the migraine attack. Despite widespread clinical use since 1926, evidence supporting the efficacy of ergotamine in migraine is inconsistent.<sup>7,14</sup>

Dihydroergotamine is available for intranasal and parenteral administration by the intramuscular, subcutaneous, and intravenous routes.<sup>2</sup> Parenteral dihydroergotamine was viewed previously as inpatient or emergency department treatment for moderate to severe migraine or intractable headache, but patients can be trained to self-administer dihydroergotamine intramuscularly or subcutaneously. Clinical opinion suggests its use is relatively safe and effective when compared with other migraine therapies.<sup>7</sup>

Nausea and vomiting (resulting from stimulation of the chemoreceptor trigger zone) are among the most common adverse effects of the ergotamine derivatives. Pretreatment with an antiemetic agent should be considered with ergotamine and intravenous dihydroergotamine therapy. Other common side effects include abdominal pain, weakness, fatigue, paresthesias, muscle pain, diarrhea, and chest tightness. Rarely, symptoms of severe peripheral ischemia (ergotism), including cold, numb, painful extremities, continuous paresthesias, diminished peripheral pulses, and claudication can result from the vasoconstrictor effects of the ergot alkaloids. Gangrenous extremities, myocardial infarction, hepatic necrosis, and bowel and brain ischemia have also been reported. Dihydroergotamine is rarely associated with such side effects.<sup>13,14,16,26</sup> Triptans and ergot derivatives should not be used within 24 hours of each other.<sup>26</sup> Ergotamine derivatives are contraindicated in patients with renal or hepatic failure; coronary, cerebral, or peripheral vascular disease; uncontrolled hypertension; sepsis; and in women who are pregnant or nursing.<sup>7,23</sup> Dihydroergotamine does not appear to cause rebound headache, but dosage restrictions for ergotamine tartrate should be observed strictly to prevent this complication.<sup>7</sup>

**Serotonin Receptor Agonists (Triptans)**

Introduction of the serotonin receptor agonists, or triptans, represented a significant advance in migraine pharmacotherapy. The first member of this class, sumatriptan, and the second-generation agents zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan are selective agonists of the 5-HT<sub>1D</sub> and 5-HT<sub>1F</sub> receptors. Relief of migraine headache is the result of three key actions: normalization of dilated intracranial arteries through enhanced vasoconstriction, peripheral neuronal inhibition, and inhibition of transmission through second-order neurons of the trigeminocephalic complex.<sup>4,12,16,28</sup> These agents also display varying affinity for 5-HT<sub>1A</sub>, 5-HT<sub>1D</sub>, and 5-HT<sub>1F</sub> receptors. The triptans are appropriate first-line therapy for patients with mild to severe migraine and are used for rescue therapy when nonspecific medications are ineffective.<sup>7</sup>

Sumatriptan, the most extensively studied acute therapy, is available for subcutaneous, oral, and intranasal administration.<sup>28</sup> Subcutaneous sumatriptan is consistently superior to placebo in alleviating migraine headache and associated symptoms, with relief reported in 69% of patients at 1 hour (48%–49% pain-free) in a meta-analysis of placebo-controlled studies.<sup>7</sup> In addition to enhanced efficacy, subcutaneous sumatriptan has a more rapid onset of action when compared with the oral formulation.<sup>7,28</sup> The subcutaneous injection is packaged as an autoinjector device for self-administration by patients. Intranasal sumatriptan provides a faster onset of effect than the oral formulation and produces similar rates of response (relief in 61% of patients at 2 hours) in placebo-controlled studies.<sup>7</sup>

The second-generation triptans appear to offer an improved pharmacokinetic and pharmacodynamic profile compared with oral sumatriptan. In general, these agents have higher oral bioavailability and longer half-lives than oral sumatriptan, which theoretically could improve within-patient treatment consistency and reduce headache recurrence<sup>7,16,28</sup> (Table 70–7). Frovatriptan and naratriptan have the longest half-lives and a slower onset of action compared with other triptans. This may make them more suitable for patients that have migraine attacks of a slow onset and longer duration. Faster-acting triptans are better when a rapid onset is necessary. Despite the fact that oral absorption can be delayed during migraine attacks, most patients prefer oral formulations, primarily due to convenience.<sup>7,16,28</sup>

Results of placebo-controlled studies with each of the second-generation agents reveal somewhat comparable 2-hour response rates. Direct comparative clinical trials are necessary to determine their relative efficacy, but these are available for only a few of the triptans. A recent meta-analysis summarizes the efficacy and tolerability of the oral triptans across published and unpublished studies. At all marketed doses, the oral triptans are effective

and well tolerated. Across studies for sumatriptan 100 mg, mean results were a 2-hour headache response of 59%, with 29% pain-free at 2 hours, 20% sustained pain-free, and 67% consistency. Compared with sumatriptan 100 mg, rizatriptan 10 mg showed better efficacy and consistency and similar tolerability; eletriptan 80 mg showed better efficacy, similar consistency, but lower tolerability; almotriptan 12.5 mg showed similar efficacy at 2 hours but better other results; naratriptan 2.5 mg and eletriptan 20 mg showed lower efficacy and better tolerability; and zolmitriptan 2.5 and 5 mg, eletriptan 40 mg, and rizatriptan 5 mg all showed similar results. Available data suggest lower efficacy for frovatriptan, although it has the longest half-life of the triptans.\textsuperscript{7,17,28}

Clinical response to the triptans can vary considerably among individual patients. Individual responses cannot be predicted, and if one triptan fails, a patient can be switched successfully to another triptan.\textsuperscript{7} After an effective agent and dose have been identified, subsequent treatments should begin with that same regimen. Combination therapy may also improve response rates and diminish migraine recurrence. A proprietary formulation of sumatriptan 85 mg plus naproxen 500 mg in a single tablet was more effective in clinical trials for headache relief and sustained pain-free response than either agent as monotherapy.\textsuperscript{16,25}

Side effects to the triptans are common but usually mild to moderate in nature and of short duration. Adverse effects are consistent among the class and include paresthesias, fatigue, dizziness, flushing, warm sensations, and somnolence. Local side effects are reported with the subcutaneous (minor injection-site reactions) and intranasal (taste perversion, nasal discomfort) routes. Up to 15% of patients receiving a triptan consistently report “chest symptoms,” including tightness, pressure, heaviness, or pain in the chest, neck, or throat. The mechanism of these symptoms is unknown, but a cardiac source of pain seems unlikely in most patients.\textsuperscript{15,26} However, all triptans are partial agonists of human 5-HT coronary artery receptors in vitro, resulting in a small but significant vasoconstrictor response. Adverse cardiac events are rare with only isolated cases of myocardial infarction and coronary vasospasm with ischemia reported. Myocardial ischemia is unlikely in patients with normal coronary vasculature because 5-HT\textsubscript{1B} receptors mediate less than 25% of the overall vasoconstrictor potential of the coronary vessels.\textsuperscript{17} The triptans are contraindicated in patients with a history of ischemic heart disease (e.g., angina pectoris, Prinzmetal’s angina, or previous myocardial infarction), uncontrolled hypertension, and cerebrovascular disease. Patients at risk for unrecognized coronary artery disease should use triptans with caution. Postmenopausal women, men older than 40 years of age, and patients with uncontrolled risk factors should receive a cardiovascular assessment prior to triptan use and have initial doses administered under medical supervision.\textsuperscript{16,25} Triptans are also contraindicated in patients with hemiplegic and basilar migraine. The triptans should not be given within 24 hours of the ergotamine derivatives. Administration of sumatriptan, rizatriptan, and zolmitriptan within 2 weeks of therapy with monoamine oxidase inhibitors (MAOIs) is not recommended. Eletriptan should not be administered with ciprofloxacin P450 3A4 inhibitors such as macrolide antibiotics, antifungals, and some antiviral therapies. Concomitant therapy with the selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) (e.g., duloxetine, venlafaxine, mirtazapine, and sibutramine) can potentially cause serotonin syndrome. Regulatory agencies caution against concurrent administration although it appears the likelihood of CNS adverse events is extremely low. The potential risk of these combinations should be carefully considered and discussed with the patient.\textsuperscript{16,26,29} Frequent use of the triptans has been associated with the development of medication-misuse headache.\textsuperscript{14,15}

## PROPHYLACTIC PHARMACOLOGIC THERAPY

### α-Adrenergic Antagonists

α-Adrenergic antagonists are among the most widely used drugs for migraine prophylaxis. Propranolol, nadolol, timolol, atenolol, and metoprolol have proven efficacy in controlled clinical trials, reducing the frequency of attacks by 50% in 60% to 80% of patients\textsuperscript{16} (see Table 70–5). Because the relative efficacy of the individual agents has not been established, selection of an α-blocker can be based on α-selectivity, convenience of the formulation, and tolerability. α-Blockers with intrinsic sympathomimetic activity are ineffective for migraine prophylaxis.\textsuperscript{16} Although their precise mechanism of antimigraine action is unknown, α-blockers may raise the migraine threshold by modulating adrenergic or serotoninergic neurotransmission in cortical or subcortical pathways. Though not first-line treatment for hypertension or anxiety, α-blockers may be useful along with other therapy in patients with comorbid anxiety, hypertension, or angina.\textsuperscript{23} Side effects can include drowsiness, fatigue, sleep disturbances, vivid dreams, memory disturbance, depression, impotence, bradycardia, and hypotension. α-Blockers should be used with caution in patients with congestive heart failure, peripheral vascular disease, atrioventricular conduction disturbances, asthma, depression, and diabetes.\textsuperscript{7,19,23}

### Antidepressants

The beneficial effects of antidepressants in migraine are independent of their antidepressant activity and may be related to downregulation of central 5-HT\textsubscript{1A} receptors, increased levels of synaptic norepinephrine, and enhanced endogenous opioid receptor actions.\textsuperscript{20} Amitriptyline, the most widely studied antidepressant for migraine prophylaxis, has demonstrated efficacy in placebo-controlled and comparative studies.\textsuperscript{19} Use of other antidepressants is based primarily on clinical and anecdotal experience (see Table 70–5). Other tricyclic antidepressants (TCAs) that have been used successfully for migraine prophylaxis include doxepin, nortriptyline, and protriptyline.\textsuperscript{19} Anticholinergic side effects are common and limit use of these agents in patients with benign prostatic hyperplasia and glaucoma. Evening doses are preferred because of associated sedation. Increased appetite and weight gain can occur. Orthostatic hypotension and cardiac toxicity (slowed atrioventricular conduction) also are reported occasionally. The more favorable side-effect profile of nortriptyline and protriptyline could prove advantageous in patients who are particularly intolerant of the anticholinergic and sedative side effects of amitriptyline.\textsuperscript{19}

SSRIs have not been studied extensively or proven consistently effective for the preventive treatment of migraine headaches.\textsuperscript{19,23} Fluoxetine is the most studied SSRI for migraine prevention, but definitive benefit has not been demonstrated in a rigorous clinical study. Prospective data evaluating the other SSRIs (e.g., sertraline, paroxetine, fluvoxamine, and citalopram) are lacking.\textsuperscript{2,19,30} These agents should not be considered as first- or second-line medications for the management of migraine, but they may be useful in patients with comorbid depression combined with, for example, an anticonvulsant for migraine prophylaxis.\textsuperscript{23} A recent study suggests a possible benefit with venlafaxine, a SNRI.\textsuperscript{20} Again, the potential risk of serotonin syndrome should be considered in patients using SSRIs or SNRIs along with a triptan.\textsuperscript{16,29}

MAOIs, such as phenelzine, have been used in the management of refractory headache, but their complex adverse-effect profile limits their use to experienced prescribers. Strict adherence to a tyramine-free diet is necessary to avoid potentially life-threatening hypertensive crisis.\textsuperscript{19,22} The reader is referred to Chapter 77 for dietary and concurrent medication restrictions for patients taking MAOIs.
Anticonvulsants

Anticonvulsant medications have emerged as important therapeutic options for migraine prophylaxis with valproate, divalproex, topiramate, and gabapentin all demonstrating efficacy. The beneficial effects of these agents are likely caused by multiple mechanisms of action, including enhancement of γ-aminobutyric acid (GABA)–mediated inhibition, modulation of the excitatory neurotransmitter glutamate, and inhibition of sodium and calcium ion channel activity.\textsuperscript{21,26} Anticonvulsants are particularly useful in migraineurs with comorbid seizures, anxiety disorder, or manic-depressive illness.\textsuperscript{19} The efficacy of valproic acid and divalproex sodium (a 1:1 molar combination of valproate sodium and valproic acid) has been demonstrated in multiple placebo-controlled studies. Nausea and vomiting, the most common early side effects, are self-limited and appear to be less common with divalproex sodium and gradual titration of doses. Alopecia, tremor, asthenia, somnolence, and weight gain are also common complaints.\textsuperscript{7,17} The extended-release formulation of doses. Weight loss, occurring in 9% to 12% of patients, is a unique adverse effect, as weight gain is a common reason to discontinue other preventive medications. Topiramate should be used with caution in patients with a history of kidney stones.\textsuperscript{19,31} Localized injections of botulinum toxin type A have been used for various conditions and pain syndromes, including migraine headache. However, no consistent, statistically significant benefits have been found with migraine. The American Academy of Neurology concludes that botulinum toxin is probably ineffective.\textsuperscript{11,12} Further study is needed to confirm the clinical utility and comparative efficacy of these miscellaneous agents for the prophylactic management of migraine.

Calcium Channel Blockers

The calcium channel blockers generally are considered second- or third-line options for preventive treatment when other drugs with established clinical benefit are ineffective or contraindicated. Verapamil is the most widely used calcium channel blocker for preventive treatment, but it provided only modest benefit in decreasing the frequency of attacks in two placebo-controlled studies.\textsuperscript{7,19} The therapeutic effect of verapamil may not be noted for up to 8 weeks after initiation of therapy. Side effects of verapamil can include constipation, hypotension, bradycardia, atrioventricular block, and exacerbation of congestive heart failure. Evaluations of nifedipine, nimodipine, diltiazem, nilodipine, nicardipine, and amlopidine have yielded equivocal results.\textsuperscript{17,19,21}

NSAIDs

NSAIDs are modestly effective for reducing the frequency, severity, and duration of migraine attacks, but potential gastrointestinal and renal toxicity limit the daily or prolonged use of these agents.\textsuperscript{17,20} Consequently, NSAIDs have been used intermittently to prevent headaches that recur in a predictable pattern, such as menstrual migraine. Administration of NSAIDs in the perimenstrual period can be beneficial in women with true menstrual migraine. NSAIDs should be initiated 1 to 2 days prior to the expected onset of headache and continued during the period of vulnerability.\textsuperscript{23,24} If long-term NSAID therapy is initiated, monitoring of renal function and occult blood loss is necessary.

Miscellaneous Prophylactic Agents

A double-blind, placebo-controlled study demonstrated the efficacy of riboflavin (vitamin B\textsubscript{2}) 400 mg daily in migraine prophylaxis. Riboflavin was well tolerated and associated with 50% or greater improvement in attack frequency in 54% of patients. However, the benefits of therapy became significant only after 3 months.\textsuperscript{19,31} The angiotensin-converting enzyme inhibitor lisinopril and the angiotensin II receptor blocker candesartan provided effective migraine prophylaxis in recent double-blind, placebo-controlled, crossover studies of these agents.\textsuperscript{19,31} Further research is needed to establish the safety and efficacy of the herbal medication feverfew (Tanacetum parthenium) because studies to date have yielded inconsistent and conflicting results.\textsuperscript{19,31} At least two placebo-controlled studies have concluded that petasites, an extract from the plant Petasites hybridus, may be an effective preventive treatment for migraine.\textsuperscript{19,31} Coenzyme Q10 was effective for migraine prevention and well tolerated in a small, randomized, double-blind, controlled study.\textsuperscript{19,31}

Clinical trials evaluating various formulations of magnesium for migraine prevention have yielded mixed results. CNS levels of magnesium are known to be significantly low during migraine attacks. Magnesium supplementation may be particularly effective for prevention of menstrual migraine and in migraine patients with aura.\textsuperscript{19,31} Localized injections of botulinum toxin type A have been used for various conditions and pain syndromes, including migraine headache. However, no consistent, statistically significant benefits have been found with migraine. The American Academy of Neurology concludes that botulinum toxin is probably ineffective.\textsuperscript{11,12} Further study is needed to confirm the clinical utility and comparative efficacy of these miscellaneous agents for the prophylactic management of migraine.

PHARMACOECONOMIC CONSIDERATIONS

Although migraine is widely recognized as a disease that exacts an enormous toll on the sufferer, the direct and indirect costs associated with migraine headache impose a substantial burden on society as well. The direct medical costs associated with clinic visits for headache and migraine diagnosis and treatment are substantial, exceeding $1 billion per year. Migraine also results in high use of
TENSION-TYPE HEADACHE

EPIDEMIOLOGY

Tension-type headache is the most common type of primary headache, with an estimated 1-year prevalence ranging from 31% to 86%. Prevalence peaks in the fourth decade and is higher among women. The incidence decreases with age. Although an estimated 60% of tension-type headache sufferers experience some degree of functional impairment during their attacks, less than 15% of sufferers seek medical attention, likely because most have infrequent attacks. Infrequent episodic tension-type headache (defined as fewer than one episode per month) is experienced by 64% of sufferers, while 22% have frequent episodic tension-type headache (episodes on 1–14 days per month). The prevalence of chronic tension-type headache (≥15 days per month, perhaps without recognizable episodes) is estimated at 0.9% to 2.2%. Risk factors associated with a poor outcome in tension-type headache include coexisting migraine, sleep problems, not being married and the presence of chronic tension-type headache.

PATHOPHYSIOLOGY

Although tension-type headache is the most common type of headache, it is the least studied of the primary headache disorders, and there is limited understanding of key pathophysiologic concepts. Some evidence supports that migraine and tension-type headaches represent a continuum of headache severity with similarities in mechanisms and pathophysiology. However, more recently, tension-type headache has been recognized as a distinct disorder. The mechanism of pain in chronic tension-type headache is thought to originate from myofascial factors and peripheral sensitization of nociceptors. Central mechanisms also are involved. Mental stress, nonphysiologic motor stress, a local myofascial release of irritants or a combination of these may be the initiating stimulus. Following activation of supraspinal pain perception structures, a self-limiting headache results in most individuals owing to central modulation of the incoming peripheral stimuli. Chronic tension-type headache can evolve from episodic tension-type headache in predisposed individuals due to a change in central circuits and nociceptive processing along the brainstem reflex pathway and subsequent sensitization of the CNS. It is likely that other pathophysiologic mechanisms also contribute to the development of tension-type headache.

CLINICAL PRESENTATION

Premonitory symptoms and aura are absent with tension-type headache. The pain usually is mild to moderate in intensity and often is described as a dull, nonpulsatile tightness or pressure. Bilateral pain is most common, but the location can vary (frontal and temporal pain are most common; occipital and parietal regions also may be affected). The pain is classically described as having a “hatband” pattern. Associated symptoms generally are absent, but mild photophobia or phonophobia may be reported. The disability associated with tension-type headache typically is minor in comparison with migraine headache, and routine physical activity does not affect headache severity. Palpation of the pericranial or cervical muscles can reveal tender spots or localized nodules in some patients. Tension-type headache is classified as either episodic (infrequent or frequent) or chronic based on the frequency and duration of the attacks.

TREATMENT

GENERAL APPROACH TO TREATMENT

The vast majority of episodic tension-type headache sufferers self-medicate with over-the-counter medications and do not consult a
healthcare professional. Although pharmacologic and nonpharmacologic treatments are available, simple analgesics and NSAIDs are the mainstay of acute therapy. Most agents used for tension-type headache have not been studied in controlled clinical trials.35

NONPHARMACOLOGIC THERAPY

Psychophysiologic therapy and physical therapy have been used in the management of tension-type headache. Behavioral therapies can consist of reassurance and counseling, stress management, relaxation training, and biofeedback. These therapies (alone or in combination) can result in a 35% to 50% reduction in headache activity.36 Evidence supporting physical therapeutic options, such as heat or cold packs, ultrasound, electrical nerve stimulation, stretching, exercise, massage, acupuncture, manipulations, ergonomic instruction, and trigger point injections or occipital nerve blocks, is somewhat inconsistent. However, individual patients may benefit from selected modalities in reducing the frequency of tension-type headache or during an acute episode.35

PHARMACOLOGIC THERAPY

Simple analgesics (alone or in combination with caffeine) and NSAIDs are effective for the acute treatment of most mild to moderate tension-type headaches. Acetaminophen, aspirin, ibuprofen, naproxen, ketoprofen, and ketorolac have demonstrated efficacy in placebo-controlled and comparative studies.35 Failure of over-the-counter agents can warrant therapy with prescription drugs. High-dose NSAIDs and the combination of aspirin or acetaminophen with butalbital or, rarely, codeine are effective options. Use of butalbital and codeine combinations should be avoided when possible owing to the high potential for overuse and dependency. As with migraine headache, acute medication should be taken for episodic tension-type headache no more than 9 days per month to prevent the development of chronic tension-type headache.36 There is no evidence to support the efficacy of muscle relaxants in the management of episodic tension-type headache.36 Preventive treatment is appropriate for most patients with chronic tension-type headache and should be considered in those with frequent episodic tension-type headache if frequency (>2 per week), duration (>3–4 hours), or severity results in medication overuse or substantial disability.36 The principles of preventive treatment for tension-type headache are similar to those for migraine headache. TCAs are prescribed most often for prophylaxis, but other drugs also can be selected after consideration of comorbid medical conditions and respective side-effect profiles. SSRIs are not effective in patients with tension-type headache who do not have depression, however, limited studies support the use of the SNRIs mirtazapine and venlafaxine.34,36 Injection of botulinum toxin into pericranial muscles has demonstrated inconsistent efficacy in the prophylaxis of tension-type headache and because of this, it is not recommended for use.32,36

CLUSTER HEADACHE

EPIDEMIOLOGY

Cluster headache, the most severe of the primary headache disorders, is characterized by attacks of severe, unilateral head pain that occur in series lasting for weeks or months (i.e., cluster periods) separated by remission periods usually lasting months or years.2,37 Cluster headaches can be episodic or chronic.2 Cluster headache is relatively uncommon among the primary headache disorders, but the exact prevalence is uncertain. The prevalence varies from 56 to 401 per 100,000.37 Men are more likely than women to have cluster headache, and onset generally occurs after age 20.37 Recent genetic epidemiological surveys support a predisposition for cluster headache can exist in certain families.97,38

PATHOPHYSIOLOGY

The etiologic and pathophysiologic mechanisms of cluster headache are not completely understood. The cyclic nature of attacks implicates a pathogenesis of hypothalamic dysfunction with resulting alterations in circadian rhythms.8 Hypothalamus-regulated changes in cortisol, prolactin, testosterone, growth hormone, leuteinizing hormone, endorphin, and melatonin have been found during periods of cluster headache attack.8,41 Neuroimaging studies performed during acute cluster headache attacks have demonstrated activation of the ipsilateral hypothalamic gray area, implicating the thalamus as a cluster generator.4 Significant cranial autonomic activation occurs ipsilateral to the pain, through the same pathways that are activated during migraine.8

CLINICAL PRESENTATION

Attacks occur in cluster periods lasting 2 weeks to 3 months in most patients, followed by long pain-free intervals.2,39 Periods of remission average 2 years in length but have been reported to be from 2 months to 20 years in duration. Approximately 10% of patients have chronic symptoms with attacks recurring for over 1 year without remission or with remission periods of less than 1 month.2,39 Cluster headache attacks occur commonly at night and more commonly in the spring and fall.39 Attacks occur suddenly, with pain peaking quickly after onset and generally lasting 15 to 180 minutes.2 Auras are not present with cluster headaches. The pain is excruciating, penetrating, and of a boring intensity in orbital, supraorbital, and temporal unilateral locations.2,39,40 The headache can be accompanied by conjunctival injection, lacrimation, nasal stuffiness, rhinorrhea, eyelid edema, facial sweating, miosis/ptosis, and restlessness or agitation. During the cluster period, attacks occur from once every other day to eight times per day.2,39,40 Whereas migraine patients retreat to a quiet dark room, cluster headache patients generally sit and rock or pace about the room clutching their head.39 There is a male preponderance in cluster headache, especially in the chronic form, and lifestyle habits such as smoking and consumption of alcohol or coffee are common.39 Specific diagnostic criteria for cluster headaches are provided within the IHS classification system.2

TREATMENT

Cluster Headaches

As in migraine, therapy for cluster headaches involves both abortive and prophylactic therapy. Abortive therapy is directed at managing the acute attack. Prophylactic therapies are started early in the cluster period in an attempt to induce remission. Patients with chronic cluster headache can require prophylactic medications indefinitely.

ABORTIVE THERAPY

Oxygen

The standard acute treatment of cluster headache is inhalation of 100% oxygen by nonbreather facial mask at a rate of 7 to 10 L/min for 15 to 30 minutes.41 Repeat administration can be necessary because of recurrence, as oxygen appears to merely delay, rather than abort, the attack in some patients.41 No side effects have been reported with the use of oxygen, but caution should be used for those who smoke or have chronic obstructive pulmonary disease.
**Ergotamine Derivatives**

All forms of ergotamine have been used in cluster headaches, although no controlled clinical trials support their use. In clinical use, intravenous dihydroergotamine results in the quickest response, and repeated administration for 3 to 7 days can break the cycle of frequent attacks. Ergotamine tartrate also has provided effective relief of cluster headache attacks when administered sublingually or rectally, but the pharmacokinetics of these preparations frequently limit their clinical utility. Dosing guidelines are similar to those for migraine headache therapy.

**Triptans**

The quick onset of subcutaneous and intranasal triptans make them safe and effective abortive agents for cluster headaches. Subcutaneous sumatriptan (6 mg) is the most effective agent. Nasal sprays are less effective but may be better tolerated in some patients. Adverse events reported in cluster headache patients are similar to those seen in migraineurs. Orally administered triptans have limited use in cluster attacks because of their relatively slow onset of action; oral zolmitriptan (10 mg), however, was beneficial in patients with episodic cluster headache with 60% experiencing mild or no pain at 30 minutes.

**Verapamil**

Verapamil, the preferred calcium channel blocker for the prevention of cluster headaches, is effective in approximately 70% of patients. The beneficial effects of verapamil often appear after 1 week of therapy. A typical suggested dosage range is from 360 to 720 mg/day, with some patients requiring up to 1,200 mg/day.

**Lithium**

Lithium carbonate is effective for episodic and chronic cluster headache attacks and can be used in combination with verapamil. A positive response is seen in up to 78% of patients with chronic cluster headache, and in up to 63% of patients with episodic cluster headache. The usual dose is 600 to 1,200 mg/day, with a suggested starting dose of 300 mg twice daily. Optimal plasma lithium levels for prevention of cluster headache have not been established, but trough values should not be more than 1.0 mEq/L (mmol/L).

Initial side effects are mild and include tremor, lethargy, nausea, diarrhea, and abdominal discomfort. Thyroid and renal function must be monitored during lithium therapy. Lithium should be administered with caution to patients with significant renal or cardiovascular disease, dehydration, pregnancy, or concomitant diuretic or NSAID use.

**Ergotamine**

Ergotamine, once commonly used, can be efficacious for prophylactic as well as abortive therapy of cluster headaches. A 2-mg bedtime dose is often beneficial for the prevention of nocturnal headache attacks. Daily use of 1 to 2 mg ergotamine alone or in combination with verapamil or lithium can provide effective headache prophylaxis in patients refractory to other agents with little risk of ergotism or rebound headache. Although there is more literature on methysergide, a serotoninergic agent related to ergotamine, as a prophylactic treatment for cluster headache, this agent is no longer available.

**Corticosteroids**

Corticosteroids are useful for inducing remission. Therapy is initiated with 40 to 60 mg/day prednisone and tapered over approximately 3 weeks. Relief appears within 1 to 2 days of initiating therapy. To avoid steroid-induced complications, long-term use is not recommended. Headaches can recur when therapy is tapered or discontinued.

**Miscellaneous Agents**

Other therapies that have been used in the acute management of cluster headache include intranasal lidocaine, hyperbaric oxygen, and subcutaneous octreotide. Limited studies or case reports also support the use of divalproex sodium, topiramate, gabapentin, intranasal cavidine, intranasal capsaicin, tizanidine, baclofen, melatonin, transdermal clonidine, leuprolide, and intramuscular botulinum toxin for cluster prophylaxis. Neurosurgical intervention can be necessary for patients with chronic cluster headache that is resistant to all medical therapies.

**Evaluation of Therapeutic Outcomes**

Patients should be monitored for frequency, intensity, and duration of headaches, as well as any change in the headache pattern. To this end, migraineurs should be encouraged to keep a headache diary to document the frequency, severity, and duration of migraine attacks, as well as response to medication and potential trigger factors. Careful monitoring is essential to initiate the most appropriate pharmacotherapy, document therapeutic successes and failures, identify medication contraindications, and prevent or minimize adverse events. Patients using acute therapies should be monitored for frequency of use of prescription and over-the-counter medications to identify potential medication-misuse headache. Patient counseling is necessary to allow for proper medication use (e.g., self-injection with sumatriptan), to encourage early use of medications in the headache cycle, and to enhance patient compliance. Strict adherence to dosing guidelines should be stressed to minimize potential toxicity. Patterns of abortive medication use can be documented to establish the need for prophylactic therapy. Prophylactic therapies also should be monitored closely for adverse reactions, abortive therapy needs, adequate dosing, and compliance. Consultation with other healthcare practitioners should be encouraged when changes in headache patterns or medication use occur.

**Conclusions**

Although headache disorders such as migraine and cluster headaches appear to occur as a result of neuronal dysfunction, the precise etiology and nature of the dysfunction are unknown. Serotonergic neurotransmission and the trigeminovascular system appear to play important roles. A careful patient workup, including patient history, physical examination, and appropriate laboratory tests, should identify most headache patients with major disease. A variety of strategies can be helpful for managing migraine, tension-type, and cluster headaches. Management of primary headache disorders is directed at suppressing acute attacks and preventing recurrences. Continuing research will better define pathophysiologic mechanisms and aid the search for less toxic and more efficacious pharmacologic agents.

Patients with psychiatric conditions are treated in all healthcare settings. All clinicians need to develop basic skills in psychiatric assessment to provide the best care for their patients.

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) is the most widely accepted diagnostic reference. It, along with the American Psychiatric Association Practice Guidelines for the Psychiatric Evaluation of Adults, provides the clinician a standardized approach for the initial assessment and follow-up of patients with mental illness.

At times, patients suffering from mental illness are challenging to assess, as their condition can prevent them from full cooperation. A range of strategies can be used to gather the needed information while maintaining the safety and comfort of both patient and clinician.

A thorough medication history to identify all medications currently taken, as well as those previously taken, is a cornerstone of effective patient management. In addition, it must be determined whether there was an adequate trial (dose and duration) of current and prior medications for psychiatric illnesses.

A baseline mental status examination, along with a specific target symptom list, is a critical tool in monitoring response to treatment.

Several papers have been published in recent years recommending specific physical assessment and laboratory tests needed for the evaluation of patients with psychiatric conditions. Except for patients taking antipsychotics, no single standard exists, and testing is individualized based on the patient’s age, medical history, current physical health, and current medication use; and in consideration of the most recent expert opinion.

Baseline and follow-up monitoring for metabolic disturbances should be instituted for all patients taking antipsychotics.

Patients with mental illnesses are treated by clinicians from many disciplines and in all settings of healthcare, and they often receive the bulk of their care from nonpsychiatrists. Hence the need for good psychiatric assessment skills is not limited to mental health specialists. Along with traditional assessments used across all medical specialties (e.g., laboratory tests, medical history, and physical examination), psychiatric practitioners use additional strategies to manage their patients that are perhaps less objective in nature and less familiar to nonpsychiatric practitioners. This chapter provides a basic overview of appropriate assessment techniques used by clinicians to develop an individualized treatment plan for psychiatric patients. Readers needing greater depth than the materials provided in this chapter are referred to other sources.

OVERVIEW OF THE DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) is the most widely accepted and most important diagnostic reference used in the care of the mentally ill. It provides a common language for practitioners to describe and diagnose psychiatric disorders. Common language is essential because there is considerable overlap of symptoms across many diagnoses. The Diagnostic and Statistical Manual of Mental Disorders, First Edition (DSM-I) was introduced in 1952 and was the first manual on mental disorders to contain a description of diagnostic categories. The most recent edition, DSM-IV-TR, was released in 2000 and uses essentially the same diagnostic criteria sets as the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV). Its purpose is to correct factual errors in DSM-IV and update the text sections (e.g., associated features, prevalence, and differential diagnosis) with more contemporary data. A more
significant rewriting of diagnostic criteria and introduction of new diagnoses will appear in Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V), which probably will not be available until May 2015. The DSM-IV-TR contains many components that provide a comprehensive understanding of specific mental illnesses and assist in making an accurate diagnosis. For example, the multiaxial patient evaluation ensures that most factors that could contribute to, or complicate, the condition are considered during a patient assessment and throughout treatment planning. Axis I lists the principal psychiatric disorder (e.g., schizophrenia, etc.), developmental disorders, or provisional diagnoses present in the patient. Mental retardation and personality disorders (e.g., antisocial, borderline, etc.) are listed on Axis II. Axis III lists existing physical disorders or conditions. Axis IV lists the severity of psychosocial stressors that might have contributed to a new or recurrent mental disorder or exacerbation of an existing condition. Stressors are rated on a scale of 1 (none) to 6 (catastrophic) and can be acute (lasting less than 6 months) or enduring (lasting longer than 6 months). Examples of stressors include difficulties with interpersonal relationships, parenting, occupation, living circumstances, finances, the legal system, and health. Axis V describes the global assessment of functioning (GAF), rated on a scale from 1 (persistent danger to self or others) to 90 (minimal or absent symptoms). A GAF rating is made based on the current level of functioning and can be used to describe the highest level of functioning achieved prior to the current evaluation. By documenting the baseline level of functioning, the GAF helps evaluate progress toward a patient’s therapeutic goals.

DSM-IV-TR provides general information on all mental disorders recognized by the American Psychiatric Association (APA) and includes age of onset, clinical course, complications, predisposing factors, prevalence, and differential diagnoses. The specific diagnostic criteria for each mental illness and the number of symptoms required to establish a diagnosis are also listed. The DSM-IV-TR also includes decision trees for differential diagnosis and a glossary of technical terms. The Clinical Interview Using DSM-IV is a companion publication that provides extensive information on interviewing techniques helpful in establishing a specific DSM-IV diagnosis.

Additional information besides the DSM-IV-TR diagnosis is required before a comprehensive treatment plan can be developed. The American Psychiatric Association Practice Guidelines for Psychiatric Evaluation of Adults (2nd edition) includes a full discussion of the domains needed for a thorough clinical evaluation. It also discusses issues of privacy, appropriate setting for assessment, and evaluations in special populations.

In summary, the DSM-IV-TR and the APA practice guidelines allow clinicians to evaluate patients in a systematic manner, thereby creating better treatment plans and a more consistent evaluation of response.

THE CLINICAL INTERVIEW

The interview should be conducted in a quiet, nonstimulating, and comfortable area where the patient and the interviewer feel at ease. The setting should be appropriate to the patient’s level of acuity and the potential for risk to the patient and clinician. The interviewer should introduce himself or herself and explain what is about to happen in order to establish a trusting relationship. Generally, open-ended questions come first, followed by questions focused on more specific or personal data. Open-ended questions allow the patient to provide descriptions and other information in his or her own words. Even though more specific questions may then be necessary to fill in the gaps, beginning in this manner minimizes the risk of “leading” the patient. Patients can respond to specific questions and “yes” or “no” questions with answers they think the interviewer wants to hear. The interviewer must be nonjudgmental about the information offered by the patient to develop trust and rapport and to ensure completeness and accuracy of the information. Whether a clinician takes notes or just listens during the interview is an individual decision, with the primary considerations being to make an accurate record of the content of the examination and assuring that the patient is comfortable with the note taking. Table 71–1 provides examples of questions useful for gathering information during the completion of the clinical interview.

| **Mania** | 1. Do your thoughts go faster than you can say them?  
2. Have you noticed a change in the amount of sleep that you require?  
3. Have you spent a lot of money lately, and what did you spend it on?  
4. Do you have a lot of extra energy?  
5. Do you feel more active than usual?  
6. Do you feel your life is not worth living?  
7. Is there a reason for your waking up?  
8. Do you have trouble falling asleep?  
9. Do you ever have a lot to do?  
10. Do you feel your life is not worth living? |
| **Depression** | 1. Do you feel that people plot against you?  
2. Do you ever feel that you are watched or spied on?  
3. Do you have any special abilities?  
4. Does anyone ever try to mess with you or bother you?  
5. Do others read your thoughts?  
6. Have you ever seen anything strange that you can’t explain?  
7. Have you ever heard your name called when there is no one there?  
8. Have you ever seen things that bother you and no one else?  
9. Do you want to act on what the voices say?  
10. Do you ever hear voices that other people don’t hear?  |
| **Schizophrenia** | 1. Do you see things improving in the future?  
2. Do you feel that others can put thoughts in your head?  
3. Do you want to act on what the voices say?  
4. Do you ever have a lot of extra energy?  
5. Do others read your thoughts?  
6. Do you feel that others can put thoughts in your head?  
7. Do you ever have a lot of extra energy?  
8. Do you feel that others can put thoughts in your head?  
9. Do you ever have a lot of extra energy?  
10. Do you feel that others can put thoughts in your head? |
| **Insight** | 1. Why do you feel that you have no friends?  
2. What brought you here?  
3. What reasons did your family give you for coming here?  
4. What do you think about your life?  
5. What do you think about your present mental state?  
6. What do you think about your future?  
7. What do you think about your past?  
8. What do you think about your present mental state?  
9. What do you think about your future?  
10. What do you think about your past? |
| **Sleep** | 1. Do you feel your life is not worth living?  
2. Do you ever think of hurting yourself?  
3. Do you see things improving in the future?  
4. Do you think you will try to hurt yourself now?  
5. How would you do it?  
6. Do you have the means to hurt yourself?  
7. Do you ever feel that you are watched or spied on?  
8. Do you have any special abilities?  
9. Does anyone ever try to mess with you or bother you?  
10. Do others read your thoughts? |

THE CHALLENGING PATIENT

Patient assessments can be challenging when symptoms of the condition prevent effective engagement with the clinician. Excited patients may exhibit speech that is rapid and unorganized; whereas, depressed patients may respond with few words. Patients in the manic phases of bipolar disorder may not pause as they speak ( pressured speech), making it difficult for the interviewer to intercept. In all cases, the interviewer can regain control by politely redirecting the patient back toward the question. Psychotic patients may be paranoid and appear guarded or frightened by the questions. The best approach is to remain calm and respectful, use shorter or closed-ended questions, and seek only essential information until the patient is less paranoid. Patients can become agitated and occasionally violent. Often violence is preceded by increased psychomotor agitation as evidenced by pacing, speaking in a loud voice, or gripping the arms of the chair. When there is concern about safety, the interviewer should avoid any behavior that could be misconstrued as threatening, such as touching or unnecessary staring, and interview the patient in the presence of another health-care provider. Both the patient and interviewer should have equal access to leave the room if either becomes too uncomfortable. If a patient becomes threatening to the interviewer, the interviewer should not hesitate to leave the room and call for help. If a patient describes suicidal thoughts, he or she should be further assessed using the questions outlined in Table 71–1, and depending on the results of further assessment should be directed to the appropriate type of care, including hospitalization for patients at immediate risk of harming themselves. A suicidal patient should never be left alone. Asking a patient about suicidal thoughts will not increase the risk. The risk is greater if these questions are never asked or signs of distress are ignored. Before any conclusions are made about a patient interview, the impact of culture on the patient’s presentation should be considered. Something that sounds delusional in Western culture can be the norm in others. If a clinician is unclear whether culture of origin accounts for some of the patient’s symptoms, he or she should consult with a family member or someone else familiar with the patient’s culture of origin.

PSYCHIATRIC HISTORY

Both the patient’s and the patient’s family history of mental illness provide important information when formulating a diagnosis and treatment plan. Information should include the current and previous psychiatric diagnoses, the clinical presentation of each illness, time frame between episodes, level of functioning between episodes, length of each episode, total duration of illness, and treatment given during each episode as well as response to those treatments. Baseline functioning or the highest level of functioning achieved in the past few years is important because it helps to define a treatment goal. Information on the history of the current episode and reasons for presenting to the clinician also should be gathered. A family history should include a medication history of the immediate relatives because a family member’s response to a given medication might predict an individual patient’s response to that same medication.

SOCIAL HISTORY

A social history should include educational and occupational background, religion, marital status, substance-use patterns including tobacco, alcohol, and caffeine, and current living situation. By understanding a patient’s living environment and social situation, strategies to foster treatment adherence, reduce stress, and increase social support can be developed. To probe this area initially, the clinician can ask patients to describe their social support network.

This can be followed by more specific questions such as “To whom are you closest?” or “In whom do you confide?”

MEDICATION HISTORY

A thorough medication history is one of the most important contributions a clinician can make to treatment planning. The history should include medications for both psychiatric and medical conditions. It should list all medications taken by the patient, and report on how each was tolerated and the nature of the response to that drug or combination of drugs. All allergies must be noted. Because most psychiatric medications have a delay in the onset of effect, it is important to determine whether an adequate trial (dose and duration) was provided before the patient was deemed “nonresponsive” to that drug. If a patient has a history of nonadherence, specific causes such as cost, complicated dosing schedules, lack of insight, and adverse effects should be investigated.

MENTAL STATUS EXAMINATION

The mental status examination (MSE) is a key patient assessment tool in psychiatry and is analogous to the physical examination in medicine. The MSE is completed through a direct patient interview and results in a description of current behavior, thoughts, perceptions, and functioning. The MSE provides an objective evaluation used in diagnosis, assessment of the course of the illness, and response to treatment. It is combined with other components of the patient workup (history of present illness, physical examination, appropriate laboratory tests, and medical and psychiatric history) to give a full picture of the presenting problem and factors contributing to the illness. The MSE has several components.5–7

Appearance and Attitude Toward Examiner

The appearance of the patient throughout the interview should be noted, including age, dress, grooming and hygiene, use of cosmetics, and facial expressions. A description of appearance also should include unusual physical characteristics and the general state of physical health. The interviewer should note whether the patient is cooperative, mute, hostile, paranoid, guarded, or withdrawn.

Activity

Motor activity may be excessive or diminished. Overactivity can include pacing; hand wringing; picking at clothing, skin, or hair; inability to sit still during the interview; and excessive hand gestures. Underactive patients move less than expected. Patients with rigid posture, an absence of movement, and failure to communicate may be catatonic, paranoid, or experiencing medication-induced adverse effects.

Speech and Language

The quantity, flow, and speed of speech and the amount of eye contact should be noted. The appropriateness and degree of eye contact varies significantly between cultures, and before poor eye contact is interpreted, the patient’s cultural background should be considered. Speech should be assessed as to whether it proceeds logically in a goal-directed manner or whether the content is vague and poorly organized. Abnormal speech characteristics include thought blocking, whereby the person suddenly stops speaking without any obvious reason. Thought blocking usually occurs when a hallucination or delusion intrudes into the person’s thinking or when upsetting issues are discussed. Circumstantial speech lacks a clear direction because of excess unnecessary information, but the circumstantial patient eventually will make his or her point. In tangential speech, however, the ultimate point is never made. Perseveration is repetition of an
original answer to subsequent questions. *Flight of ideas* is overproductive, rapid speech during which the patient jumps rapidly from one idea to the next. *Mutilism* is identified when the patient does not respond even though he or she is aware of the discussion.

**Affect and Mood**

Affect describes the patient’s current emotional tone, as expressed through facial expression, body posture, and tone of voice, all of which can be objectively observed by the clinician. Mood describes feelings, which are subjectively reported by the patient. Change in facial expression and the presence of tears, flushing, sweating, or tremors should be noted. Affect can be described further by its range, appropriateness, intensity, and stability. For example, in schizophrenia or depression, the affect can be flat, whereby no change in expression occurs throughout the interview. In contrast, during a manic episode, the affect is very intense and often excited. *Blunted affect* denotes that the range of emotional expression is reduced, but not absent. An example of *inappropriate affect* is when a patient laughs in a situation that would be expected to produce sadness. A rapidly shifting affect from one extreme to the other is described as *labile*.

**Thought and Perceptual Disturbances**

A variety of thought disturbances can occur in mental illness. Many of these disturbances generally indicate the presence of psychosis or impaired reality testing. *Delusions* are fixed, false beliefs that are not based in reality or consistent with the patient’s religion or culture. Delusions can be paranoid, somatic, or grandiose in nature. Delusions are often unshakable, and although the clinician can challenge the delusional thinking, one should not attempt to talk a patient out of a delusion. *Thought broadcasting* is the belief that one’s thoughts are audible to others. *Hallucinations* are false sensory impressions or perceptions that occur in the absence of an external stimulus. Hallucinations can be auditory, visual, olfactory, tactile, or gustatory and can be continuous or intermittent. In contrast, *illusions* are visual misperceptions involving a misinterpretation of a real sensory stimulus. For example, a person who initially misperceives a curtain blown by the wind to be an intruder has experienced an illusion. This phenomenon does not always indicate a psychiatric illness and can be seen in persons without mental illness. Not all thought disturbances are indicative of psychosis. For example, the couplet of obsessions and compulsions can indicate the presence of obsessive-compulsive disorder, which is not considered to be a psychotic disorder. *Obsessions* are unwanted thoughts or ideas that intrude into a person’s thinking. *Compulsions* are actions performed in response to the obsessions or to control anxiety associated with the obsession.

**Evaluation of Cognition**

The mental status exam assesses sensorium, attention, concentration, memory, and higher cognitive functions such as orientation and abstraction. The clinician should document whether the patient has received medications with sedative properties, because the outcome of the examination can be altered if central nervous system depressants were recently taken.

*Sensorium*, or level of consciousness, refers to the alertness of the patient, and if he or she is not fully alert, the amount of stimulation needed to awaken the patient. Attention and concentration can be assessed using serial subtraction by 7s (“serial 7s”) or 3s, or by having a patient spell a five-letter word backward. General intelligence can be assessed loosely by asking factual information about current news items, recent presidents, or popular television shows or sporting events. *Memory* is the ability to recall past experiences and is classified as sensory stores (which lasts seconds), short-term memory (the ability to recall newly acquired information after several minutes), working memory (i.e., immediate application of visual or auditory instructions), and long-term or remote memory (historical facts). Orientation to time, place, person, and situation assesses sensory stores and short-term memory. Asking a patient to recall three objects 5 minutes after they are learned is the definitive test for short-term memory. Deficits in short-term memory may be seen in depression and anxiety, but this finding is the hallmark feature of dementia. Asking the patient to do a certain task (e.g., pick up a pen with his or her right hand and then fold a piece of paper and pass it to the examiner) can assess the patient’s working memory. Patients with cognitive deficits, such as those seen in dementias and schizophrenia, can exhibit deficits in working memory. Remote memory is assessed by asking patients to recall old facts about their lives, such as where they were born or where they went to school. Remote memory usually remains intact the longest in patients with intellectual decline, whereas the ability to create new memories is generally the first sign of a memory deficit. *Abstraction* is the ability to interpret information such as a proverb (“People in glass houses shouldn’t throw stones”) or identify similarities or differences between words (e.g., apple and orange). Abstraction is influenced by education, cultures and linguistic fluency; thus inability to abstract is not always a sign of a psychiatric disorder. Persons with schizophrenia often provide *concrete* (literal or superficial interpretations) or *bizarre* responses to probes of abstraction.

**Insight and Judgment**

Insight refers to patient awareness that he or she has a mental illness and the impact of that illness on his or her life. Patients typically demonstrate a lack of insight when they are psychotic. Patients with *poor* insight are often nonadherent with prescribed medications. Judgment is the ability to make decisions appropriate to the situation and can be impaired in a variety of mental illnesses. Judgment can be assessed by asking patients how they would handle either their current or a hypothetical situation. Both insight and judgment can be fluid. For example, intoxicated patients can demonstrate *poor* insight and judgment only to improve over several hours as their blood alcohol concentration decreases.

**Physical Examination and Laboratory Assessment**

There is no consensus about specific laboratory tests for diagnosing or evaluating mental illness. The identification of biologic markers (e.g., pharmacogenomics) as diagnostic tools, predictors, or indicators of drug response is of great interest but currently of limited clinical usefulness. The most promising was the dexamethasone suppression test, proposed to be a marker for endogenous melancholic depression. However, its lack of sensitivity and specificity has limited its usefulness as a routine screening tool during a workup for depression. Although there are no tests to definitively indicate that a patient has a specific mental illness (e.g., schizophrenia or bipolar disorder), laboratory tests are important to clarify the etiology of presenting symptoms. Patients who present with psychiatric symptoms need a careful medical assessment because of overlapping symptoms. A complete physical examination, along with a detailed medical and medication history, vital signs, weight and body mass index, a pregnancy test when indicated, and routine blood chemistry are commonly part of the workup of persons with mental illness. In most cases, a physical examination should be chaperoned.

Both medical illnesses and medications can cause the same psychiatric symptoms. The rapidity of onset of psychiatric symptoms...
is an important clue that a medical cause may be present. Most chronic mental illnesses have a prodromal period, whereas medically based psychiatric symptoms generally have a more rapid onset of symptoms. Patients older than 40 years of age at first presentation are more likely to have a medical cause for their psychiatric symptoms because major psychiatric illnesses such as schizophrenia and bipolar disorder usually first present in adolescence or early adulthood. Family history can provide additional clues. Patients with fluctuating levels of consciousness, disorientation, memory impairment, or visual, tactile, or olfactory hallucinations are more likely to have a medical basis for their presentation.

Patients with psychiatric illnesses, especially depression and anxiety disorders, often present with only physical complaints, leading to inappropriate care for medical problems that are not present or as serious as they may appear, while the root cause is ignored. In contrast, patients with severe persistent mental illness (e.g., schizophrenia) have increased risks for cardiovascular disease and are less likely to receive the same level of primary medical care compared to patients without mental illness.²⁻⁴ Barriers to medical care include patient paranoia, ambivalence, and disorganization accounting for missed appointments; stigma toward mental illness; and poor communication between primary care and psychiatric clinicians.¹⁻² Antipsychotic therapy can also cause or exacerbate medical conditions, such as diabetes mellitus, hyperlipidemia, or cardiac arrhythmias, necessitating an initial assessment and ongoing monitoring for these conditions while continuing treatment.²⁻¹²

General laboratory screening is useful for ruling out medical causes of psychiatric illnesses and medication monitoring. Urine drug screens and blood alcohol tests play an important role in identifying the contribution of substances of abuse to the presenting symptoms. Additional testing can include an electroencephalogram to evaluate for the presence of seizure activity or other neurologic conditions, computed tomography or magnetic resonance imaging to detect structural abnormalities, sedimentation rate and antinuclear antibodies for autoimmune disorders, a human immunodeficiency virus test, thyroid function tests, and vitamin B₁₂ and folate concentrations for anemias.² Laboratory tests should be individualized to the age, medical/medication history, cooperativeness, and physical health of the patient, but extensive testing is usually unnecessary and not cost-effective.

Clinicians also use diagnostic tests to evaluate the relative safety of specific medications such as pregnancy monitoring with valproex, renal status when using lithium, or an electrocardiogram when using a tricyclic antidepressant such as amitriptyline. Baseline information is often needed to help document future adverse effects from medications (e.g., lithium-induced hypothyroidism, clozapine-induced leukopenia, antipsychotic-induced diabetes mellitus). Serum concentration monitoring is recommended for medications with a narrow therapeutic index such as lithium, divalproex, and carbamazepine. Serum concentration monitoring can also be useful for assessing medication adherence when there is inadequate response. With the exceptions of lithium, divalproex, and clozapine, there is minimal data to support obtaining serum concentrations for optimizing medication efficacy in psychiatric disorders.

The 2004 expert consensus recommends that patients starting on newer antipsychotic agents should be screened for symptoms of metabolic syndrome including body weight (baseline, weeks 4, 8, and 12, then every 3 months (12 weeks), then annually), waist and hip measurements (baseline and annually), blood pressures (baseline, week 12, and annually), and fasting serum lipids and glucose (if possible at baseline, week 12, and annually for high-risk patients).¹²⁻¹⁴ In 2007, it was reported that over 50% of patients on antipsychotics were not being monitored for diabetes and dyslipidemia.¹⁵ Glucose and lipid monitoring continues to be underutilized for patients taking antipsychotics. Although fasting serum results are preferred over random serum or capillary blood specimens, this should not be a barrier to adequate monitoring.¹⁶ The clinician can employ random glucose, high-density lipoprotein cholesterol levels, or glycosylated hemoglobin A₁c if there is difficulty obtaining fasting serum levels.¹¹⁻¹³

In summary, a range of assessments aid the clinician in making problem-focused workups to verify diagnoses and identifying underlying or potential drug-related problems.¹⁷ The MSE is the cornerstone of the psychiatric workup, although selective medical tests, a good medical, psychiatric, and medication history, and a thorough physical examination are also important.

### PSYCHIATRIC RATING SCALES

Psychiatric rating scales are useful tools to provide an objective way of measuring subjective data (e.g., feelings, thoughts, and perceptions) and to screen or diagnose specific disorders. As there are so many types of scales to choose from, the clinician rater needs training and experience to select and use the most appropriate scale. Rating scales are used in a variety of settings, including research and patient care, and can serve an administrative purpose such as quality control.⁹

Drawbacks to the more frequent use of clinician-rated scales include the substantial time commitment for staff to administer the tests and the inability of some patients to tolerate these interviews, especially patients who are severely paranoid or agitated. In addition, repeated ratings are usually necessary to objectively describe longitudinal changes over a defined treatment period as opposed to a snapshot of a complex clinical situation.

Some rating scales are self-administered (patient-rated) and do not require a staff member to collect the data; thus they require minimal resources to administer and can provide valuable information, although some patients may be unable to self-administer a questionnaire for a variety of reasons, including limited literacy and severity of symptoms.

In contrast to symptom-based rating scales (e.g., Positive and Negative Syndrome Scale or Hamilton Depression scale), global rating scales, such as the Clinical Global Impression scale, assess the overall severity of illness based on a rater’s clinical experience.¹⁸⁻²⁰ In general, these rating scales measure the presence or severity of symptoms and can assist in the diagnostic formulation.

Rating scales are also available to measure adverse side effects from psychiatric medications. Specific adverse side-effect measures can be used for specific categories of medications. Table 71–2 provides a summary of the most common rating scales used to assess and quantify the presence and severity of adverse effects.²¹

Sensitivity, specificity, reliability, and validity are important considerations when selecting a rating scale. Sensitivity refers to a test’s ability to detect a symptom or illness, given that the symptom or illness is present. Specificity refers to a test’s ability to determine that a symptom or illness is absent given that the person does not have the illness.

Reliability is the extent to which the score on the scale reflects the hypothetical “true” score and how much interference occurs from outside influences.²² Reliability is reported by the correlation coefficient, which represents a chance correlation (zero) or perfect correlation (1). Rating scales with correlation coefficients of less than 0.7 are usually considered unreliable for clinical studies. Interrater reliability—agreement in rating scores among clinician raters—is important to achieve when multiple clinicians rate the same patient or population. Interrater reliability is established by having all raters independently rate individual patients at the same time to determine the correlation of their scores.

EPS, extrapyramidal symptoms.

Data from Schoeler and Chengappa,21 and Guy.19

Validity, in contrast, is the ability of a scale to measure what it was designed to measure. Various validity tests are performed on a rating scale to ensure that the scale assesses the appropriate aspects of the illness (content validity), the correlation with diagnoses or clinical change (concurrent validity), and the extent to which the scale measures symptom traits in contrast to a specific symptom (construct validity).

Psychiatric rating scales should not be confused with psychologic tests such as neuropsychologic and intellectual assessments and are best used as only one part of a comprehensive diagnostic plan. Tables 71–3, 71–4, and 71–5 describe commonly used patient-rated and clinician-rated scales for a variety of disease states.10–20,23–26

### SYSTEMATIC MEASUREMENT OF COGNITIVE FUNCTION

Neuropsychiatric rating scales provide specific information such as the rate of change and severity of cognitive decline or improvement. They are useful in situations in which repeated measurements of a patient’s mental status are needed because they allow the clinician to determine response to an intervention (e.g., medication) in a more systematic manner. In addition, some cognitive function measures are useful screens for Alzheimer disease and other causes of cognitive decline. A number of cognitive rating scales are available, the most common being the Mini-Mental Status Examination (MMSE).

The MMSE is a structured interview that globally assesses many cognitive domains, including orientation, visuospatial organization, memory, and reasoning to determine an overall score of cognitive function. The maximum score is 30, and a score of 23 or less is indicative of significant cognitive impairment. The MMSE takes 5 to 10 minutes to administer and is used routinely in the clinical setting.27 Other examples of cognitive rating scales include the Blessed Information Memory Concentration test (BIMC), the Dementia Rating Scale (DRS-2), the Clock Drawing test (CDT), and Alzheimer’s Disease Assessment Scale.28–31

Most of the rating scales involve a structured interview that requires clinician training to ensure accurate administration. Noise and distraction can affect the patient’s performance ability; therefore, the interview should be conducted in a quiet area with adequate lighting. The interviewer should speak slowly and clearly to the patient when providing instructions or asking questions.

### PSYCHOLOGICAL TESTING

Although most clinicians do not administer psychological testing, they can use the results to evaluate the role of medication in relationship to the diagnosis. Psychological testing alone cannot establish a firm diagnosis but can be a useful diagnostic tool when coupled with clinical judgment. Types of psychological testing include personality tests (e.g., Minnesota Multiphasic Personality Inventory-2), intelligence tests (e.g., Wechsler Adult Intelligence Scale–Revised, Wechsler Intelligence Scale for Children–Revised), projective tests (e.g., Rorschach), and neuropsychologic tests (e.g., Bender Visual Motor Gestalt Test).3

CONCLUSIONS

Patient assessment is the basis from which a pharmaceutical care plan evolves. Problem identification and therapeutic monitoring cannot occur until a thorough assessment is completed. The initial assessment provides the basis for evaluating response to therapy throughout the course of treatment. Psychiatric assessment requires empathy and good listening skills on the part of the clinician because it is based primarily upon subjective interpretation and not objective tests. With careful data collection, clinicians can make substantial contributions to care that improve patient outcomes.

ACKNOWLEDGEMENTS

The authors are grateful to Patricia A. Marken, PharmD, FCCP, BCPP, Professor of Pharmacy Practice at the University of Missouri--Kansas City, College of Pharmacy, for her significant contributions to this chapter in previous editions.

KEY CONCEPTS

1. Inattention and impulsivity caused by attention deficit/hyperactivity disorder (ADHD) begins before age 7 years and can continue into adolescence and adulthood, often requiring ongoing drug treatment.

2. Stimulants are first-line treatment for ADHD because they are the most effective medications and have overall good tolerability. Atomoxetine, guanfacine extended release (XR), and bupropion are second-line alternatives for those unresponsive to or unable to tolerate stimulants. Clonidine and guanfacine can also be considered as adjuncts to stimulants to optimize treatment of oppositional symptoms or persistent insomnia.

3. Coexisting disorders or symptoms such as anxiety, mood, and behavior dysregulation have an impact on drug selection for ADHD and can necessitate the use of additional agents.

4. Tourette's disorder presents with both motor and vocal tics, which are present during childhood, plateau during adolescence, and can continue during adulthood with a fluctuating course.

5. The decision to medicate patients with Tourette's disorder is based on the degree of concern perceived by the patient, symptom severity, and comorbid disorders.

6. Individuals with Tourette's disorder are particularly sensitive to medication side effects, so medication dosing must be individualized carefully, and close monitoring is essential.

7. Nondrug approaches to enuresis management, such as behavioral interventions and the use of bed-wetting alarms, are preferred because of lasting cure rates and avoidance of drug side effects.

8. Desmopressin tablets are preferred over tricyclic antidepressants (TCAs) because of better safety and tolerability. Both desmopressin and TCAs have a rapid onset of effect (1–2 weeks); however, the relapse rate on drug discontinuation is high.

All neuropsychiatric disorders can first present during childhood.1 Attention deficit/hyperactivity disorder (ADHD), Tourette's disorder, and enuresis are the focus of this chapter because, by definition, the onset of symptoms explicitly occurs during childhood.

Treating children with psychotropic drugs requires a very different approach than treating adults. Children undergo neurologic, physiologic, and psychosocial changes throughout development. Age-related pharmacodynamic and pharmacokinetic differences can alter drug disposition and response. Well-defined diagnostic criteria guide drug selection;1 however, comorbid disorders present treatment challenges.2,3 Children may not be able to articulate symptom response or adverse effects of a medication. Psychotropic drug treatment of children is intended to control symptoms or behaviors that impair learning and development.2,3

The psychiatric assessment of a child requires obtaining information from the child, parents, caregivers, and teachers.

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

A diagnosis of ADHD should be considered whenever a child presents with developmentally inappropriate inattention, impulsivity, and/or hyperactivity. Symptom presence and severity vary with the situation. It is unusual for a child to display signs of the disorder in all settings or even in the same setting at all times.1

CLINICAL PRESENTATION AND EPIDEMIOLOGY

1. The onset of ADHD is typically by the age of 3 years and must occur by age 7 to meet the diagnostic criteria of the Diagnostic and Statistical Manual of Mental Disorders (Fourth Edition, Text Revision; DSM-IV-TR). However, recent studies in adults are challenging the age of onset criteria, suggesting little difference in functional impairment and response to methylphenidate in adults who meet onset criteria before age 7 and those who meet all criteria except age of onset.5 ADHD occurs in 6% to 9% of children and is estimated to be present in 4% of adults.3,4 In the United States, four boys are diagnosed with ADHD for every girl. This difference is likely because of higher rates of oppositional defiant disorder and conduct disorder in boys, compared with girls; thus, referrals for assessment are higher for boys. Symptoms can persist lifelong for both sexes, but hyperactivity is much less prominent in adolescence and adulthood.3,6

CLINICAL PRESENTATION OF ADHD

General

- Onset of symptoms must be before 7 years of age.

Symptoms

- Six or more of the symptoms must be present for 6 months; significant impairment must be seen in two or more settings
Inattention and distractibility can be symptoms of an anxiety, mood, or psychotic disorder. In some cases, other disorders coexist with ADHD; learning deficiencies and conduct or oppositional disorders are common comorbid conditions. The presence of multiple comorbid conditions, particularly conduct or mood disorder, can increase the likelihood of ADHD chronicity into adulthood.

Prescriptions for ADHD medication are increasing in all age groups, particularly in adolescents and young adults. A National Poison Control Center study estimates that between 1998 and 2005, prescriptions for teenagers and preteenagers increased 133% for amphetamine products and 52% for methylphenidate products, 80% for both.

**ETIOLOGY AND PATHOPHYSIOLOGY**

Both genetic and nongenetic factors are implicated in the pathogenesis. First-degree relatives of an individual with ADHD have a four- to eightfold increased chance of developing ADHD compared with the general population; monozygotic twins have up to a 90% concordance rate for ADHD. Children with fetal alcohol syndrome, lead poisoning, and meningitis have a higher incidence of ADHD symptomatology. ADHD is associated with a variety of environmental risks, including obstetric adversity, maternal smoking, and adverse parent–child relationships. Dietary causes are unlikely.

Although there are no definitive pathophysiologic markers for ADHD, imaging studies show subjects with ADHD have decreased total brain volume relative to controls in multiple brain regions (right prefrontal cortex, caudate nucleus, anterior cingulate gyrus, and cerebellum). Global thinning of the cortex has been observed in children with ADHD, and comparative studies show there is a delay in cortical thickening in ADHD brains relative to age-matched controls. These brain changes are thought to impair executive functioning necessary for prioritization of tasks, decision making, motor control, and an awareness of space and time. Alterations in the “default mode” attention network have been found in adults with ADHD. A lack of connectivity between the prefrontal cortex and precentral (located in the midline of the parietal lobe) is associated with failure of suppression of the default mode network, causing lapses in attention and inhibitory control.

Genetically mediated changes in serotonergic, cholinergic, and most notably dopaminergic function have been documented in children and adults with ADHD. Deficits in the dopaminergic reward pathway in the ADHD brain impair the ability to delay gratification, resist distractions, regulate arousal, and attend to information or tasks that are dull or repetitive. This dysfunction involves multiple dopaminergic receptors (D2, D3, D4, and D5) and dopamine active transporter protein (DAT), which is presynaptic. Norepinephrine and epinephrine are agonists at dopaminergic receptors and are modulated by DAT as well. Treatment with stimulants has been shown to improve the rate of cortical thickening, and pharmacotherapy can improve or normalize dopaminergic receptor function. Those with demonstrated abnormalities in DAT seem to respond better to methylphenidate and atomoxetine.

Effective treatments modulate dopamine and norepinephrine to improve executive functioning, regulate arousal, and sustain attention for improved performance. The clinical response associated with stimulants is not paradoxical and is not diagnostic for ADHD because stimulants can increase attention, decrease motor activity, and improve learning tasks in those with subclinical ADHD or in individuals with such problems from other sources (e.g., fatigue).

### TREATMENT

#### STIMULANTS

Stimulants are considered first-line therapy in most cases of ADHD; however, comorbid conditions impact the drug selection process. Pharmacotherapy should be considered whenever a thorough diagnostic assessment results in a diagnosis of ADHD. Several studies demonstrate the superiority of stimulants over behavioral interventions in alleviating core symptoms of ADHD. Emerging literature shows improvement in academic performance in medicated children with ADHD versus those unmedicated. One National Institutes of Health (NIH) study of 594 fifth graders with ADHD showed those medicated (greater than 90% took stimulants) had 2.9 points higher math scores and 5.4 points higher reading scores compared with unmedicated children. Another study involving 363 10- to 18-year-olds with ADHD showed medication improved but did not normalize cognition.

Multimodal treatment, individualized to the specific needs of the child and family, is crucial for an overall positive therapeutic outcome. Table 72–1 describes behavioral interventions for ADHD. Multimodal treatment includes parent training, family therapy, classroom interventions, and contingency management (e.g., rewards for good behavior). Figure 72–1 provides an algorithm for drug selection in the treatment of ADHD.

Stimulants (e.g., methylphenidate, dextimethylphenidate, mixed amphetamine salts, and dextroamphetamine) are the most effective drug treatment options, with efficacy ranging from 70% to 96%.

Methylphenidate and amphetamines block dopamine and norepinephrine reuptake; amphetamines also increase catecholamine release. Both drugs inhibit monoamine oxidase (MAO), or
amphetamines, more potently than methylphenidate. Because different stimulants work through slightly different mechanisms, the lack of response to one chemical class of stimulant (e.g., methylphenidate or dexmethylphenidate) does not preclude response to another class (e.g., dextroamphetamine or mixed amphetamine salts).

Stimulant dosing should be titrated for maximum individual efficacy and minimum side effects (see Table 72–2). With immediate-release stimulants, most patients require a two or three times daily dosing schedule because of the short half-lives of these drugs (2–4 hours for methylphenidate and dexmethylphenidate and ~4–6 hours for dextroamphetamine or mixed

| ADVERSE EFFECTS | | | |

The most common adverse effects of stimulants and their management strategies are listed in Table 72–3. Uncommon to rare but potentially serious adverse effects are discussed in the following sections.
Growth

Two reviews that analyzed approximately 32 studies indicated that stimulant treatment of ADHD can affect growth, but the effects are minimal or insignificant for most children. A study of 579 children showed a decrease of ~1 cm/year (~0.5 inch) in height over 1 to 3 years of continuous treatment with methylphenidate and a weight deficit of 3 kg (6.6 lbs) in the first year of treatment and 1.2 kg (2.6 lbs) in the second year of treatment. Amphetamine products may be associated with more prominent growth effects than methylphenidate according to separate studies. Proposed mechanisms of stimulant effects on growth include alterations in growth hormone or growth factor, decreased thyroxine secretion, and suppression of appetite leading to reduced caloric intake. In most cases, children should be given a drug-free trial every year. Time off stimulant appears to lessen stimulant growth suppressant effects, but evidence is lacking to firmly determine the impact of drug holidays on growth. Consideration must be given to the risks of negative effects on learning, socialization, and self-image while off stimulant therapy when determining the frequency and duration of the drug-free trial. Drug holidays are important because they provide time to reassess the need for continued treatment. Drug dosage often varies from year to year, largely because of age-related pharmacokinetic changes. As a child develops, hepatic metabolism slows, and volume of distribution increases.

Psychiatric

The Food and Drug Administration (FDA) has added warnings to the labeling of all stimulants and atomoxetine. Hundreds of postmarketing reports of three broad categories of psychiatric adverse events have been associated with stimulants: psychosis or mania, aggression or violent behavior, and severe anxiety or panic attacks. All of these reactions require dose reduction or cessation of stimulant therapy and supportive treatment.

Cardiac

A boxed warning for cardiovascular risks including sudden unexplained death has been added to ADHD stimulant drug labeling. Clinical trial data show that children who take stimulants for ADHD can have an increased heart rate by ~5 beats/minute and/or increased blood pressure by 2 to 7 mm Hg. A 10-year review showed a 20% increased risk for emergency department visits for cardiac symptoms in those taking either methylphenidate or amphetamine. Of note, these individuals were more likely to have a coexisting anxiety disorder.

Stimulant products generally should not be used in pediatrics or adults with known structural cardiac abnormalities. The American Heart Association recommends careful screening of all children and adolescents prior to initiating pharmacologic therapy for ADHD, including a detailed patient and family history and physical examination. Ideally, a baseline electrocardiogram (ECG) should also be obtained, along with routine monitoring of pulse and blood pressure. The FDA did not find the risk of sudden unexplained death to be greater in those taking stimulants than in the general population; therefore, no restriction in stimulant use has been recommended.

**NONSTIMULANTS**

Extended-release atomoxetine and guanfacine are second-line alternatives to the stimulants for treatment of ADHD in children and adolescents. Atomoxetine is also approved in adults. Their potential benefits relative to stimulants include no abuse potential, less potential for growth effects, and less sleep disturbance. See Table 72–4 for dosing.

Atomoxetine is a selective norepinephrine reuptake inhibitor that should be taken in divided doses in the morning or late afternoon by children for improved tolerability. Adults can take it once daily, usually in the morning. Placebo-controlled, short-term trials (6–12 weeks) have shown that atomoxetine is effective in reducing ADHD symptoms in children, teens, and adults, and 9-month continuation studies show ongoing benefit for responders. A controlled trial comparing atomoxetine, oral osmotic methylphenidate, and placebo over 6 weeks in 6- to 16-year-old patients showed that both drugs were significantly better than placebo at improving ADHD symptoms, but oral osmotic methylphenidate was superior to atomoxetine.

Atomoxetine has a significantly slower onset of therapeutic effect than stimulants (2–4 weeks vs 1 hour with an effective stimulant dose). Atomoxetine is sometimes combined with a stimulant in partially responsive patients based on case series describing fewer late-day rebound effects and better sleep when atomoxetine is given in the evening; however, adverse effects are additive.

Guanfacine and clonidine are central α2-adrenergic agonists, acting both presynaptically to inhibit norepinephrine release and postsynaptically to increase blood flow in the prefrontal cortex. Increased blood flow in the prefrontal cortex has been shown to enhance working memory and executive functioning. Both interact with a multitude of neurotransmitter systems, including catecholamine, indolamine, α1-receptors on parasympathetic neurons, opioids, imidazole, and amino acid systems. Guanfacine has a longer elimination half-life (12–18 hours) compared with clonidine (2.5–4 hours), and its greater selectivity for the α1-receptor, compared with clonidine, imparts less sedation. Clonidine and immediate-release guanfacine are not as effective as stimulants for monotherapy treatment. They are prescribed frequently as...

</table>

ADHD = attention deficit/hyperactivity disorder, ECG = electrocardiogram, SR = sustained release, XL = extended-length.  
*Short-term use (1–4 months) only for severe aggression associated with ADHD.

Adjuvants to reduce disruptive behavior, control aggression, or improve sleep.3,4,6

Extended-release guanfacine is approved for children and adolescents based on two large placebo-controlled trials involving over 300 patients each and long-term safety studies.26,27 It appears at least as effective as other nonstimulants and is an acceptable second-line agent for children and adolescents unresponsive to or unable to tolerate stomach upset or insomnia with stimulant medications. Extended-release guanfacine is more sedating than stimulants or atomoxetine; therefore, sleepiness during the school day requires careful monitoring.

Bupropion, a monosynaptic antidepressant, is a weak dopamine and norepinephrine reuptake inhibitor with no significant direct effect on serotonin or MAO. Its active metabolites augment noradrenergic and dopaminergic function. Investigations with bupropion in children demonstrated efficacy greater than placebo in two controlled trials and efficacy comparable with methylphenidate (n = 15 children) in another controlled trial.5,4 Bupropion has less appetite suppression compared with stimulants but has a greater risk of seizures. It also may be effective in adults at antidepressant doses.3,4,6

Tricyclic antidepressants (TCAs) are last-line agents because they are the most dangerous in overdose and pose the greatest risk for cardiovascular side effects.6 Impiramine and desipramine are the most systematically studied TCAs in the treatment of ADHD, although nortriptyline is also effective.6,6 The onset of TCA clinical response occurs within the first 2 to 4 weeks.6,6

Variability in dosage requirements for atomoxetine, bupropion, and TCAs can be due to interpatient variability in plasma concentration achieved at a given dose. All are metabolized via cytochrome P450 (CYP) 2D6, and bioavailability and half-life can be 4 to 8 times greater in those taking a CYP2D6 inhibitor (e.g., bupropion, fluoxetine, or paroxetine) or in poor metabolizers. For example, atomoxetine’s half-life is 5 hours in extensive metabolizers and 19 hours in poor metabolizers.3,6 Bupropion is metabolized faster in prepubertal children, making twice daily dosing optimal for efficacy (even for bupropion SR). It Twice-daily dosing of atomoxetine is optimal in children and adolescents to improve tolerability.3,6 Once-daily dosing of bupropion or atomoxetine is possible for most adults. If tolerance develops after months of therapy, a dosage adjustment can be necessary to compensate for age-related changes in distribution and metabolism.

Lithium and anticonvulsants are used increasingly to control aggression and explosive behavior in patients with a diagnosis of ADHD. Some patients actually can have childhood-onset bipolar disorder or combined ADHD–bipolar disorder.3,6 Lithium, valproate, and carbamazepine are effective for explosive behavior, aggression, and impulsivity, but they are not beneficial treatments for a child with the inattentive subtype of ADHD. Dosing starts in low divided doses with titration over 1 to 2 weeks to therapeutic response.6,24 Conventional antipsychotics improve symptoms of hyperactivity and impulsivity but can have negative effects on learning and cognitive functioning and can cause extrapyramidal side effects.

---

SECTION 7

Psychiatric Disorders
(e.g., dystonia and tardive dyskinesia) that limit their usefulness, 3,4,6,28 The atypical antipsychotics risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole have been used to control severe aggression in refractory cases of ADHD, particularly if conduct disorder or bipolar disorder coexists. 29,30 More studies are needed to clarify their place in therapy. 6,30,28–31

If multiple drugs are started simultaneously, it is impossible to determine the impact of each drug. The predominance and urgency of symptoms guide the drug-selection process (see Fig. 72–1). For example, if a child presents as severely anxious or depressed with associated attentional problems, then an antidepressant should be initiated first with monitoring to determine if attentional symptoms improve. 3,4,6 When a child presents with severe ADHD and associated anxiety or depression, a stimulant should be initiated to treat the more severe ADHD. If ADHD symptoms improve significantly, but anxiety or depression persists, then an antidepressant can be added.3,4,6 Careful monitoring is needed to detect drug interactions that lead to higher drug plasma levels and increased adverse effects. 3,8,28 Studies show that stimulants do not routinely make anxiety disorders worse, but they might not improve symptoms either. 3 In a child with epilepsy, methylphenidate is safe and effective; however, the child should be stabilized and seizure-free on an anticonvulsant prior to initiation of the stimulant. 3,4

Adverse Effects

Possible adverse effects of atomoxetine, and their management, are similar to those of stimulants, including psychiatric and cardiac adverse effects (see Table 72–4). Atomoxetine has been associated with less growth suppression compared with stimulants, 0.44 cm over 2 years of treatment. It has a greater risk of fatigue, sedation, and dizziness compared with stimulants and bupropion. Unlike stimulants, atomoxetine labeling includes a bolder warning of potential for severe liver injury following reports in two patients. Also, it is the only FDA-approved ADHD medication with a labeled warning for new onset suicidality, 0.4% in atomoxetine treated patients versus 0% in patients receiving placebo. 3,4

The most common side effects of clonidine and guanfacine are dose-dependent sedation, hypotension, and constipation. 3,4 Sedation usually subsides after 2 to 3 weeks of therapy. 3,4,6 Of concern are reports of bradycardia, syncope, rebound hypertension, heart block, and sudden death with clonidine. 3,4,35 Four children have died on the combination of methylphenidate and clonidine; however, complicating factors make it impossible to link the drug combination directly with the cause of death. 3,5 Overdoses, concurrent clonidine and stimulant administration, and missed doses of clonidine all add to the risk of adverse cardiovascular events. 3,33 Extended-release guanfacine appears to pose a lower risk of cardiac adverse effects according to available safety data. 3,4

Bupropion’s adverse effects include nausea, which can resolve over time or with slower dosage titration, and rash, which can require discontinuation of therapy if severe (see Table 72–4). Bupropion should not be used in children with a seizure or eating disorder because of unacceptable risk of seizures in these patients. Bupropion can cause or exacerbate tics. 3,4

Possible central nervous system (CNS) adverse effects of TCAs include dizziness, aggressiveness, excitement, nightmares, insomnia, forgetfulness, and irritability. Similar to other antidepressants, TCAs carry a warning of the risk of new-onset suicidality in pediatric patients. 3,5 TCAs should be taken throughout the week and not just on school days. TCA-withdrawal effects are severe in children and include nausea, vomiting, and diarrhea. 3,2 Signs of CNS toxicity are confusion, impaired concentration, hallucinations, and delusions.

PHARMACOECONOMIC CONSIDERATIONS

A conservative annual cost of illness estimate for ADHD in 2005 dollars was calculated at $14,576 per child (range $12,000–$18,000). This estimate includes lost work for parents; the cost of special education, behavioral interventions, medications, and doctor and clinic visits; and the use of the juvenile justice system. 39 A large study found behavioral interventions were more expensive than immediate-release stimulant medication initially, but the long-term effects (e.g., lower rates of delinquency and substance abuse) lower costs. Atomoxetine was found most cost effective for those who could not take stimulants due to a lack of efficacy or poor tolerability. 39

Once-daily stimulants are approximately 3 to 5 times as expensive as immediate-release formulations, but they can save money over time with improved adherence and symptom control. A retrospective analysis comparing immediate-release methylphenidate use patterns with oral osmotic methylphenidate use patterns in 5,939 patients over 34 months found that its use was associated with longer treatment periods, increased patient adherence, and fewer emergency room visits for injury, potentially decreasing overall costs. 38

EVALUATION OF THERAPEUTIC OUTCOMES

Careful documentation of baseline symptoms and complaints over a 1-month predrug period is essential to the evaluation of therapeutic and adverse outcomes. Investigation regarding family history of psychiatric disorders and cardiac disease is essential to determine risk for related adverse drug reactions and to implement appropriate monitoring. 34 Baseline symptoms can be measured using videotapes, clinician rating scales (e.g., ADHD rating scale IV, Vanderbilt ADHD diagnostic scale), or both. 34 In addition, height, weight, and eating and sleeping patterns should be recorded at baseline and every 3 months. 3,4

After the initiation and titration of any drug treatment, it is necessary that parents, teachers, and clinicians assess the overall functioning of the child using standardized rating scales to determine if significant therapeutic benefit justifies continuing medication. 34 Therapeutic effects of the stimulants include decreased motor activity and impulsivity and increased attention span. 3,4,13,14 This suggests that stimulants are indicated for ADHD symptoms and not for primary learning disorders. The benefits of drug therapy must outweigh the potential for adverse effects. 3,4,6,7

Substance Abuse

ADHD itself is a known risk factor for the development of a substance use disorder. 3,7 A 3-year outcome study confirmed results of earlier studies by showing that children with ADHD as a whole were at least twice as likely to engage in substance abuse compared with non-ADHD controls. 3,5 Drug therapy was not associated with substance abuse in this study; however, drug therapy was associated with higher rates of delinquency at 36 months. Conduct disorder increased the risk of delinquency and substance abuse. 3,7

Studies show nontreated or inadequately treated adolescents and adults with ADHD are at increased risk of substance abuse compared with those who are effectively treated with drug therapy. 3,39 Another study showed that children with later onset of methylphenidate initiation (ages 8–12 years) had greater substance use compared with those starting treatment earlier. It is possible that early treatment of ADHD has a protective effect toward the emergence of conduct disorder, which usually precedes antisocial personality disorder and increases the risk for delinquency and drug abuse. 3

Atomoxetine and bupropion also require monitoring to detect changes in appetite, weight, and sleep patterns, as well as pulse or
blood pressure. An adequate trial of atomoxetine or bupropion consists of 6 weeks at maximum tolerated doses unless response occurs at a lower dose.\textsuperscript{3,4,6}

**CLINICAL CONTROVERSY**

The use of stimulants to treat ADHD in individuals with substance abuse disorders is controversial. A diagnosis of ADHD confers at least a twofold greater risk of adolescent and adult substance abuse.\textsuperscript{3,4,14} The risk is greater if conduct disorder, antisocial personality, or bipolar disorder coexists.\textsuperscript{3,4,7} Stimulant therapy does not increase the risk of substance abuse, and effective treatment of ADHD can facilitate functioning and reduce abuse. Regardless of the benefits, however, there is significant misuse or diversion of stimulant medications among older adolescents and young adults, necessitating vigilance among prescribers and careful risk-versus-benefit assessment.\textsuperscript{3,4,9}

When guanfacine or clonidine is given, careful clinical monitoring for fatigue, dizziness, and autonomic changes (e.g., blood pressure and pulse) is recommended.\textsuperscript{3,4} The American Heart Association has stated that electrocardiographic monitoring is not required for clonidine treatment in children, although many clinicians continue to assess for ECG changes.\textsuperscript{33} When discontinuing treatment, clonidine and guanfacine should be withdrawn slowly (0.05 mg clonidine/0.5 mg guanfacine reductions every 3 days) to prevent rebound hypertension or behavioral dyscontrol.\textsuperscript{3,4} A therapeutic trial requires 1 to 2 months to assess therapeutic response, although increased sleep usually occurs immediately.

The effects of TCAs on the ECG should be monitored carefully. Of more concern are reports of sudden death in children taking desipramine or imipramine.\textsuperscript{3,4,52} Children and adolescents given TCAs should have pretreatment and follow-up ECGs to assess the effects of TCA therapy on cardiac rate and rhythm.\textsuperscript{3,4,52}

**CONCLUSION**

In summary, the preferred first-line drug therapy for ADHD is either methylphenidate, dextmethylphenidate, mixed amphetamine salts, or dextroamphetamine. Extended-release atomoxetine and guanfacine are good options for those unresponsive to or unable to tolerate stimulants. Bupropion is a safer option than a TCA, but both are declining in use, given that FDA-approved treatments are better studied. All agents require careful cardiovascular monitoring. Mood stabilizers (e.g., lithium, divalproex, and carbamazepine) and atypical antipsychotics are adjuncts for control of aggression or comorbid bipolar disorder. Other agents require further investigation before their status in the treatment of ADHD can be fully determined.

**TOURETTE’S DISORDER**

**EPIDEMIOLOGY AND CLINICAL PRESENTATION**

Tourette’s disorder, also known as Tourette Syndrome, is present in 0.7% to 1% of boys and 0.4% of girls.\textsuperscript{40,41} The essential features of this CNS disorder are multiple motor and vocal tics that must be present for more than 1 year before the diagnosis of Tourette’s disorder is made. A tic is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization.\textsuperscript{40,41} The clinical presentation can vary from barely noticeable to debilitating, and the type of tic expressed can change over time.\textsuperscript{1,4,10,41}

**CLINICAL PRESENTATION OF TOURETTE’S DISORDER**

**General**

- Onset occurs before 18 years of age.

**Symptoms**

- Multiple motor or one or more vocal tics are present.
- Motor and vocal tics do not need to occur concurrently.
- Tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year; during this time, there is never a tic-free period of more than 3 consecutive months.

**Motor Tics**

- Eye blinking, lip licking
- Facial twitching
- Shoulder shrugging
- Squatting, twirling

**Vocal Tics**

- Clicks, grunts
- Barking, yelping
- Throat clearing, echolalia
- Coprolalia, palilalia

Data from American Psychiatric Association.\textsuperscript{1}

More than 90% of children with Tourette’s disorder have coexisting conditions such as ADHD (75%), mood disorders (60%), obsessive-compulsive disorder (40%), other anxiety disorders, or a combination of comorbidities. Tourette’s disorder itself does not cause diminished intellectual functioning; however, the severity of tics and associated illnesses can result in significant impairment in school functioning, sometimes necessitating special education classes.\textsuperscript{40,41} A follow-up study in adults showed that the severity of vocal tics had a more negative impact on functioning than the severity of motor tics.\textsuperscript{42}

**ETIOLOGY AND PATHOPHYSIOLOGY**

Tourette’s disorder is inherited in a complex polygenic pattern. Symptoms and severity of the disorder vary from one generation to another.\textsuperscript{40,41} The neurochemical pathophysiology involves an imbalance in the interaction of dopaminergic, serotonergic, γ-aminobutyric acid (GABA)-ergic, glutamatergic, cholinergic, noradrenergic, and opioid systems in multiple brain regions, most notably the basal ganglia and caudate nucleus. The imbalance can cause a lack of regulation of the brain’s inhibitory mechanisms, resulting in tics and associated behavior disorders. This multisystem etiology best explains the success of a variety of treatments.\textsuperscript{40,41}
Whenever symptoms are severe enough to impair the child’s ability to function, drug therapy should be initiated. Psychotherapy and behavioral treatment are useful adjuncts. The α-adrenergic antagonists clonidine and guanfacine are good first-line treatment for mild motor and vocal tics associated with Tourette’s disorder. Their milder side effect profile compared with dopaminergic blocking drugs and efficacy for anxiety and insomnia can be an advantage. In some patients, however, the response is limited to improvement in attention and behavior with no changes in the frequency of tics. Clonidine can be initiated at 0.05 mg at bedtime with weekly titration to response. The goal dose of clonidine is 0.1 mg three times daily to a maximum of 0.2 mg three times daily. Guanfacine can be initiated at 0.5 mg at bedtime with a goal dose of 1 mg twice daily to a maximum of 1 mg three times daily. Case reports describe a positive response from the clonidine patch as well. The onset of therapeutic effects for both clonidine and guanfacine is slow, ranging from 2 weeks to a few months.

Dopamine-blocking antipsychotic drugs (haloperidol, fluorphenazine, pimozide, and risperidone) are the most effective drug treatment options for managing motor and vocal tics associated with Tourette’s disorder, but they carry the risk of extrapyramidal side effects. A controlled trial showed risperidone 3.8 mg/day was more effective than pimozide 2.9 mg/day and was associated with fewer extrapyramidal side effects. A Cochrane database review of pimozide for Tourette’s disorder showed it was slightly less effective than haloperidol but comparable in efficacy to risperidone. Uncontrolled data show benefit from olanzapine, ziprasidone, and aripiprazole. All have sufficient dopamine type 2 (D₂) blockade to exert therapeutic benefit.

Therapy with risperidone, pimozide, or haloperidol should be initiated at very low doses of 0.25 to 0.5 mg/day given at bedtime and then increased gradually. Gradual titration over 2 to 3 weeks helps minimize extrapyramidal and sedative effects while permitting careful assessment of response. Symptoms can regress within 48 to 72 hours after an effective dose is reached. Doses less than 5 mg/day are effective in controlling tics for most patients.

The decision to treat Tourette’s disorder with a D₂ receptor antagonist (atypical or conventional) rather than an α₂-agonist is controversial and can be challenging. The choice is usually based on whether high efficacy (D₂ antagonist) or milder adverse effect burden (α₂-agonist) is more desirable in an individual patient.

Therapeutic trials (6–12 weeks) of a selective serotonin reuptake inhibitor (SSRI) or clomipramine should be added to tic-specific therapy when obsessive-compulsive, anxiety, or depressive symptoms cause functional impairment in patients with Tourette’s disorder. Careful monitoring for behavioral activation, disinhibition, and motor restlessness is essential during SSRI or clomipramine therapy, because these symptoms can indicate increased risk for suicidal behavior or a switch to mania, requiring drug discontinuation.

For those who are unresponsive, partially responsive, or unable to tolerate dopamine antagonists or α₂-agonists, several adjuncts or alternative treatments are available. Clonazepam, topiramate, and baclofen appear to offer promise in relieving tics and associated symptoms. Extensive clinical experience with the dopamine-depleting drug tetrabenazine shows improvement in motor and vocal tics, but controlled trials are needed. Seven patients with antipsychotic-resistant tics and antibodies to caudate nucleus protein received single transfusions of immunoglobulin, which caused remission of motor and vocal tics for more than 6 months. Botulinum toxin injected into the vocal cords has improved severe vocal tics, but controlled trials are needed.

Tourette’s and ADHD
Pharmacotherapy with stimulants increases dopaminergic and noradrenergic activity, which has the potential to aggravate or precipitate tics, although short- and long-term studies in 71 children showed no worsening of tics with methylphenidate dosed up to 0.5 mg/kg/day. Studies examining the comparative effects of methylphenidate and dextroamphetamine on tics in children found the majority experienced improvement in ADHD symptoms with acceptable effects on tics. Methylphenidate was better tolerated than dextroamphetamine.

A double-blind, placebo-controlled trial compared methylphenidate or clonidine monotherapy to combination methylphenidate and clonidine in patients with ADHD and Tourette’s disorder. Combination therapy demonstrated the greatest benefit in reducing symptoms of ADHD and tics (P < 0.0001). Clonidine appeared most helpful for impulsivity and hyperactivity, whereas methylphenidate was most helpful for inattention. All treatments were well tolerated, but sedation was common (28%) in those receiving clonidine. Patients and caregivers should be aware of the risks of using stimulants in children with Tourette’s disorder (see ADHD section); careful monitoring is essential.

A controlled trial of atomoxetine versus placebo in 117 children with ADHD and Tourette’s disorder over 18 weeks showed treatment with atomoxetine 0.5 to 1.5 mg/kg/day improved symptoms of both, with overall good tolerability. Treatment-emergent nausea, decreased appetite, decreased body weight, and increased heart rate occurred significantly more often in those receiving atomoxetine compared with those receiving placebo.

Clonidine or guanfacine alone are less effective alternatives to stimulants in the treatment of children with Tourette’s disorder and ADHD. Guanfacine was administered to 34 children (mean age 10.4 years), with ADHD and tic disorder during an 8-week placebo-controlled trial at a dose of 1.5 to 3 mg/day. Tic severity decreased by 31% in the guanfacine group compared to 0% in the placebo group. There was a mean improvement of 37% on the teacher-rated ADHD scale compared with 8% improvement with placebo. Because of its similarity to clonidine, guanfacine’s cardiovascular effects warrant careful clinical monitoring.

Results from these studies concur with the Texas Children’s Medication Algorithm for ADHD, which recommends a stimulant (preferably methylphenidate) or atomoxetine as first-line treatment for ADHD in children with Tourette’s disorder or chronic tics.

Tourette’s and Anxiety or Mood Disorders
Pharmacotherapy of Tourette’s disorder is challenging because of the common occurrence of coexisting disorders typically requiring medication combinations. Often the behavioral problems precede and are more disturbing than the involuntary movements, making them a treatment priority.

Comorbidity
Pharmacotherapy of Tourette’s disorder is challenging because of the common occurrence of coexisting disorders typically requiring medication combinations. Often the behavioral problems precede and are more disturbing than the involuntary movements, making them a treatment priority.

Clinical Controversy
The decision to treat Tourette’s disorder with a D₂ receptor antagonist (atypical or conventional) rather than an α₂-agonist is controversial and can be challenging. The choice is usually based on whether high efficacy (D₂ antagonist) or milder adverse effect burden (α₂-agonist) is more desirable in an individual patient.
vocal tics in case reports, but it requires further study.\textsuperscript{40} For truly severe and refractory cases, deep brain stimulation and even neureosurgery have been effective.\textsuperscript{40} Nonpharmacologic interventions include support groups and “habit-reversal therapy.”\textsuperscript{40} Further information for patients, families, and educators is available on the Tourette’s Syndrome Association website (http://www.tsa-usa.org).

\section*{ADVERSE EFFECTS}

For clonidine and guanfacine, the most common adverse effect is sedation. Fortunately, tolerance usually develops to this effect over days to weeks. The most potentially serious side effects are cardiovascular (see the section on ADHD).\textsuperscript{3,5} Other \(\alpha_1\)-agonist side effects are dry mouth, constipation, headache, mood changes, and even a temporary worsening of tics in \(\text{\sim}10%\) of patients.\textsuperscript{3,4,3,4,3}

Atypical antipsychotics (e.g., risperidone, olanzapine, ziprasidone, and aripiprazole) pose similar adverse effect risks in children and adolescents compared with adults (see Table 72–4).\textsuperscript{3,1,4,6} Available data show that children and adolescents are at higher risk for experiencing sedation, acute extrapyramidal side effects, hyperprolactinemia, withdrawal dyskinesia, and significant weight gain during treatment compared with adults. Risperidone is associated with more weight gain in youths than adults, and ziprasidone and aripiprazole do not seem to be as “weight neutral” in pediatric populations as in adults.\textsuperscript{20,3,1,4,6} Ziprasidone carries a risk of QTc prolongation, although torsades de pointes has not been reported, and the clinical significance requires further study.\textsuperscript{20,23,43}

Adverse effects have been reported with haloperidol doses of 2 mg/day or greater. In one review of 24 patients treated with haloperidol for Tourette’s disorder, 66.7% discontinued treatment because of intolerable side effects (e.g., dysphoria, akathisia, nervousness, sedation, dystonia, and cognitive dulling or feeling drugged).\textsuperscript{49} Lowering the dose can alleviate side effects. An antiparkinsonian agent such as benztropine (at a starting dose of 0.5 mg orally twice daily) sometimes will reverse extrapyramidal side effects. Whether a patient with Tourette’s disorder is developing a new tic or tardive dyskinesia can be difficult to determine.\textsuperscript{3,4,1,4,3}

Pimozide is less likely to cause extrapyramidal side effects than haloperidol.\textsuperscript{2,4} Anticholinergic side effects can occur in addition to drowsiness, and, occasionally, anxiety will occur. ECG changes, including T- and U-wave abnormalities and prolongation of the QTc interval, are found rarely with recommended therapeutic doses of pimozide for Tourette’s disorder; however, drugs that inhibit CYP3A4 (e.g., clarithromycin and fluoxetine) should not be combined with pimozide because of the risk of pimozide elevating pimozide blood levels, which can result in lethal QTc prolongation.\textsuperscript{3,4,1,4,3}

\section*{PHARMACOECONOMIC CONSIDERATIONS}

Haloperidol provides the most economic drug therapy because of high efficacy and low cost. Pimozide and atypical antipsychotics are more expensive than generic haloperidol, and they require ECG and metabolic monitoring, respectively. Although generic clonidine is inexpensive, delayed onset of effect and significantly lower efficacy substantially increase total costs of treatment.

\section*{EVALUATION OF THERAPEUTIC OUTCOMES}

An adult outcome study involving 58 subjects with Tourette’s disorder found that 40% were currently taking medication for their symptoms. The most frequently taken medications were antipsychotics (50%), antidepressants (36%), and clonidine (23%). Anticholinergic drugs, stimulants, and benzodiazepines were used by less than 10% of patients.\textsuperscript{42} Evaluating therapeutic interventions is challenging, as most patients can suppress their tics voluntarily for minutes to hours.\textsuperscript{45} Also, numerous factors, such as stress, concentration, and relaxation, can affect tic frequency and severity. The use of regular videotaped assessments in conjunction with standardized rating scales (Yale Global Tic Severity Scale) is helpful in objectively evaluating symptoms, side effects, and overall drug response.\textsuperscript{40–42}

Individuals with Tourette’s disorder are particularly sensitive to medication side effects, so medication dosing must be individualized with low starting doses and careful weekly titration to response, realizing that it can take 1 to 2 months for an adequate therapeutic trial. Children taking any dopamine-blocking medication should receive monitoring every 3 to 6 months for extrapyramidal effects and tardive dyskinesia with a standardized rating scale (e.g., Abnormal Involuntary Movement Scale [AIMS]).\textsuperscript{31} Patients given pimozide or ziprasidone should receive baseline and follow-up ECGs.\textsuperscript{3,4,3,4} Consult the ADHD section for additional monitoring recommendations for atypical antipsychotics.\textsuperscript{3,4,2,4,3}

\section*{CONCLUSION}

In summary, haloperidol, pimozide, and risperidone have the advantages of greatest efficacy and rapid onset in the treatment of Tourette’s disorder. Ziprasidone, olanzapine, and aripiprazole show promise; however, comparison studies with haloperidol, pimozide, and risperidone are needed to determine their relative safety and efficacy. Clonidine and guanfacine have the advantage of causing no extrapyramidal side effects, but they are significantly less effective and require ongoing cardiovascular monitoring. Drug treatment must be highly individualized, considering comorbid disorders, side effect sensitivity, and drug interactions.

\section*{ENURESIS}

The essential feature of enuresis is repeated involuntary or inappropriate voiding of urine by day or night that is not caused by a general medical condition.\textsuperscript{1}

\section*{ETIOLOGY, PATHOPHYSIOLOGY, AND CLINICAL PRESENTATION}

Medical causes of inappropriate voiding (e.g., diabetes mellitus, diabetes insipidus, seizure disorders, and urinary tract infections) should be ruled out.\textsuperscript{30,31}

\section*{CLINICAL PRESENTATION OF ENURESIS}

\begin{itemize}
  \item \textbf{General}
    \begin{itemize}
      \item Patients are 5 years old or older.
    \end{itemize}
  \item \textbf{Symptoms}
    \begin{itemize}
      \item Patients repeatedly void urine into bed and/or clothes involuntarily or intentionally.
      \item There is either a frequency of twice weekly for at least 3 consecutive months or the presence of clinically significant distress or impairment in social, academic (occupational), or other area of functioning.
    \end{itemize}
\end{itemize}

Enuresis occurs in 12% to 25% of 4-year-olds, 7% to 10% of 8-year-olds, and 2% to 3% of 12-year-olds, with 1% to 3% continuing to experience enuresis in late teenage years. After age 5 years, there is a 15% annual rate of spontaneous remission. The ratio of males to females with enuresis is 2:1. Factors that predispose a child to enuresis include a positive family history, institutionalization, low socioeconomic status, reduced functional bladder capacity, delayed or lax toilet training, constipation, psychological factors, and developmental delay. Some children with nocturnal enuresis lack the normal circadian variation in urine excretion rate, urine osmolality, and antidiuretic hormone (ADH) secretion. Nocturnal enuresis is not associated with a particular sleep stage, although children with enuresis can be more difficult to arouse.

### TREATMENT

The first steps in treating a child with enuresis are to educate the family about the high frequency of the problem, dispel any misconceptions, provide emotional support, and strongly discourage punishment.

- Continence skills and various behavioral and conditioning methods remain the primary treatments for enuresis, and drug treatment remains a secondary approach. Simple behavioral and physical interventions such as encouraging voiding at least once every 2 hours and having the child drink liberal fluids throughout the day with minimal fluids after 6 p.m. can decrease enuresis without any side effects or safety concerns. Complex interventions, such as dry-bed training in combination with bed-wetting alarms, can be tried but require time and effort. There is insufficient evidence to support complex interventions without an alarm. After 3 to 4 months of using a bed-wetting alarm, enuresis is cured in two-thirds of children.

Alarms are more effective than pharmacotherapy with longer lasting results, although medications work faster, within 2 weeks. Combining medications and alarms has been tried with mixed results. Desmopressin tablets are preferred to TCAs (e.g., imipramine) because of greater efficacy and lower toxicity risk. Oxybutynin and tolterodine may be effective adjuncts to desmopressin in partial responders, but they are not as effective as monotherapy.

#### DESMOPRESSIN

Desmopressin acetate, a synthetic analogue of the natural human ADH arginine vasopressin, is currently available in a nasal spray, which is no longer recommended, and a more widely used oral tablet for the treatment of nocturnal enuresis. Desmopressin increases overnight urinary osmotic concentration by increasing water reabsorption and reducing the volume of urine entering the bladder. It is effective in reducing the number of wet nights in 10% to 65% of children within 1 to 2 weeks, with cessation of bed-wetting in up to 48% of children; however, up to 80% relapse upon discontinuation.

In a 6-month, randomized, controlled trial comparing desmopressin (200–400 mcg), imipramine (25 mg), and combination desmopressin (200 mcg) and oxybutynin (5 mg) in 145 enuretic children (mean age 7.8 years), the combination produced the most rapid results, although the number of wet nights per month at 6 months was similar in the combination desmopressin/oxybutynin group (3.7 ± 5.4) compared with the desmopressin monotherapy group (4.0 ± 4.6). Both treatments were superior to imipramine (9.3 ± 8.3). The mean number of wet nights during the 2-week baseline period in all groups was 13. Tolerability was superior in the desmopressin groups compared with the imipramine group.

Intranasal desmopressin should not be used because of the unacceptable risk of hyponatremia, which may cause seizures. Only the tablet form is approved by the FDA for primary nocturnal enuresis. For children 6 years of age or older, desmopressin tablets can be initiated at 200 mcg at bedtime. Approximately 1% of oral desmopressin is absorbed. Plasma concentrations reach a maximum approximately 45 minutes after administration. Effective dosages range from 200 to 600 mcg/day of oral desmopressin. The duration of action varies from 10 to 20 hours, and there is compensatory polyuria the following day when the drug wears off.

#### TRICYCLIC ANTIDEPRESSANTS

Imipramine is the most studied TCA, although desipramine, amitriptyline, and nortriptyline are also effective. Imipramine is effective in increasing dry nights for up to 60% of individuals, with cessation of bed-wetting in only ~20% of children. The mechanism of action of TCAs in treating enuresis is unknown. For children 6 years of age and older, the usual starting dose is 25 mg given 30 minutes before bedtime. Doses can be increased by 25 mg weekly until response is achieved. The usual effective dosing range is 1 to 2.5 mg/kg/night, and doses should not exceed 2.5 mg/kg/night. Most children respond within the first week. Because of the risk of toxicity and death in overdose, the International Children’s Continence Society recommends that TCA be used only when all other therapies have failed.

#### ADVERSE EFFECTS

Desmopressin tablets can cause transient headache, chills, dizziness, nausea, and abdominal pain. Rarely, water intoxication, hyponatremia, and subsequent tonic-clonic seizures have been reported. From 1972 to 2005, 151 postmarketing cases of hyponatremia were reported in children with nocturnal enuresis, of whom 145 were treated with intranasal desmopressin, and 6 received tablets. When desmopressin is administered, evening fluids should be restricted 1 hour before and 8 hours after drug administration. Desmopressin tablets should be stopped during acute illnesses that may lead to fluid or electrolyte imbalance. Prompt medical assessment is needed if headache, nausea, or vomiting develops, as these could be signs of hyponatremia. Concomitant medications that may lower sodium (e.g., antidepressants and oxcarbazepine) or illnesses that change hydration status (e.g., the flu) can increase the risk of hyponatremia.

Adverse effects of TCAs are dose related and include sedation, dizziness, dry mouth, constipation, and weight gain, along with the risk of ECG changes, heart block, and lowering of the seizure threshold.

#### PHARMACOECONOMIC CONSIDERATIONS

No pharmacoeconomic studies on enuresis are available. The use of a bed-wetting alarm provides the highest overall cure rate, and drugs are a secondary approach. Several types of reusable bed-wetting alarms are available, ranging from $30 to $170 per alarm, as opposed to $90 to $130 for a 30-day supply of desmopressin. However, insurance companies commonly reimburse drug therapy, whereas most do not reimburse for alarms. Therapy with desmopressin is substantially more expensive than with TCAs because of higher cost.

#### EVALUATION OF THERAPEUTIC OUTCOMES

An accurate baseline of bed-wetting frequency must be established. A 50% or greater increase in dry nights is considered a therapeutic response. For example, if baseline dry nights are 2 out of 7 days per
week, and drug treatment results in 4 or more dry nights per week, the drug is considered effective. If only one more dry night per week occurs, and the drug is at the low end of the dosing range, a dosage increase is needed. 30,31

At least 1 week is needed to evaluate the efficacy of TCAs, and 2 weeks can be needed for evaluation of desmopressin. If drug treatment is ongoing for several months, particularly if enuresis has resolved, attempts to discontinue the drug every 3 to 6 months are recommended to assess for spontaneous remission. Slow tapering of the medication can decrease the frequency of relapse. Unfortunately, therapeutic drug efficacy does not extend beyond drug discontinuation. 30,31 Desmopressin tablets are preferred to imipramine because of better tolerability and safety. 47,48

CONCLUSION

Initially, simple interventions such as lift and awake can be implemented. A bed-wetting alarm in combination with complex behavioral interventions provides lasting cures for two-thirds of children. Drug therapy has the advantage of more rapid results, but relapse is high upon drug discontinuation. 30,31

KEY CONCEPTS

1. Clinicians who specialize in the treatment of eating disorders feel that anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified should be commonly accepted as serious mental illnesses.

2. Because the causes of eating disorders are complex, multidisciplinary treatment, including pharmacologic and nonpharmacologic interventions, are preferred to ensure a positive outcome. Although outpatient treatment is appropriate for the majority of patients, it is important to recognize the factors that indicate a need for inpatient treatment.

3. Careful medical and psychiatric assessments are needed at baseline to determine the severity of illness and the complexity of comorbid conditions.

4. In patients with anorexia nervosa, one goal is to achieve and maintain a body weight within 85% of the normal weight for age and height. If the patient is malnourished, oral refeeding with the daily caloric intake starting at 1,000 to 1,600 calories per day (4186 to 6697 J/day) and slowly titrating to 2,000 to 3,000 calories per day (8372 to 12,557 J/day) is preferred. Parenteral refeeding is a treatment of last resort.

5. Antidepressants are considered to be ineffective for the core symptoms of anorexia nervosa and are reserved for patients with mood, anxiety, and obsessional symptoms that persist after weight has improved.

6. Antidepressants can improve both mood and specific target symptoms in bulimia nervosa, but they remain adjunctive to nonpharmacologic treatments.

7. Selective serotonin reuptake inhibitors are first-line agents when medications are indicated for bulimia nervosa. Compared with other antidepressant classes, they have improved tolerability and safety, although superior efficacy has not been studied. The dose of fluoxetine in bulimia nervosa is higher (60 mg/day) than the dose usually used in depression.

8. An adequate drug therapy trial in bulimia nervosa is 4 to 8 weeks. If drug treatment fails, consider that the patient may be vomiting or using other purging methods affecting the absorption of the drug.

9. The optimal duration of antidepressant treatment for bulimia nervosa is unknown, but most clinicians continue them for 9 to 12 months in patients who respond and then reevaluate the need for ongoing medication management.

10. The American Academy for Eating Disorders has taken the firm public stance that eating disorders are and should be classified as serious mental illnesses. The spectrum of eating disorders encompasses several complex diseases, sharing the pathologic feature of overevaluation of body shape and weight. Eating disorders arise from the interaction between environmental, societal, developmental, psychosocial, genetic, and biologic factors. It is estimated that 5 to 10 million women and 1 million men in the United States alone have an eating disorder. The urbanization of society, social pressure, and obsession with perfection and being thin have led to an increasing prevalence of eating disorders, with the peak onset being between 16 and 20 years of age. Anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified (EDNOS) are the primary disorders that have been identified.

Despite an improved understanding of these cognitively and emotionally disabling and potentially fatal disorders, management remains difficult. Pharmacologic intervention is a small part of a comprehensive plan that emphasizes cognitive behavioral therapy (CBT) and psychotherapy.

EPIDEMIOLOGY

ANOREXIA NERVOSA

Anorexia nervosa occurs predominantly in girls and young women (90%) and usually presents in late adolescence (median onset 17 years of age), with new cases rarely diagnosed after age 40. The estimated prevalence of the disorder in the general population is 0.3% of females; however, a subthreshold level of symptoms is estimated to affect 0.37% to 1.3% of the population. Longitudinal management of anorexia nervosa is difficult, even in cases where weight restoration is achieved. Rates of relapse requiring hospitalization within 1 year are estimated to exceed 30%.

The promotion of the virtues of being thin is also a potentially negative environmental factor. Many websites, for example, inappropriately promote healthy lifestyle aspects of anorexia and being thin as a means of being in control, successful, and coping with life’s pressures.

BULIMIA NERVOSA

Bulimia nervosa also occurs predominantly in girls and young women (90%) and usually presents in adolescence or early adult life.
Between 1% and 4.6% of adolescent and young adult females meet the diagnostic criteria for bulimia.\textsuperscript{3,11,16,17}

**EATING DISORDER NOT OTHERWISE SPECIFIED**

EDNOS is also described in the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision; *DSM-IV-TR*).\textsuperscript{3,16} Originally designed to capture eating disorder cases that did not meet diagnostic criteria of anorexia or bulimia, it has instead developed into a diagnosis of indifference. Its prevalence is estimated at 1% to 4.7% of the population, and up to 50% of patients with an eating disorder admitted to tertiary care settings are believed to have this condition.\textsuperscript{11,18} These individuals present with symptoms characteristic of eating disorders but do not meet specific diagnostic criteria. Two examples of EDNOS are night eating syndrome (NES) and binge eating disorder (BED).

NES is most common in obesity clinic populations, often accompanied by depressive symptoms. The syndrome is defined by early morning anorexia, hyperphagia in the evening, nighttime insomnia, and subsequent early morning awakening.\textsuperscript{10,12-20} NES affects an estimated 1.5% of the general population and 8.9% to 27% of patients in obesity clinics.\textsuperscript{21-23} Patients with NES are reported to benefit from antidepressant therapy, most notably sertraline 50 to 200 mg daily.\textsuperscript{10}

Although part of the EDNOS classification, BED continues to be classified as a research diagnosis. The diagnostic criteria for BED describe recurrent episodes of binge eating without compensatory behaviors (e.g., purging, excessive exercise, or fasting). BED typically presents later in life (older than 40 years of age), and approximately one-fourth of BED patients are male.\textsuperscript{16,24}

**ETIOLOGY AND PATHOPHYSIOLOGY**

The potential etiologic or exacerbating factors for eating disorders encompass physiologic, biochemical, developmental, genetic, psychosocial, and psychiatric phenomena. The biologic basis for eating disorders is difficult to delineate because it is unclear if the biologic changes are caused by or are a result of the aberrant eating behavior.

Abnormalities of the hypothalamic-pituitary-gonadal, hypothalamic-pituitary-adrenal, and hypothalamic-pituitary-thyroid axes are described as potential causes of anorexia nervosa. Amenorrhea is found in the majority of females with anorexia, providing support for the association with gonadotropin.\textsuperscript{17} However, symptoms related to these abnormalities do not always correct with weight normalization, suggesting a primary biologic abnormality.\textsuperscript{24}

The roles of serotonin, norepinephrine, and dopamine have been studied extensively, as these neurotransmitters have important functions in controlling eating behaviors. Dysfunctions in these systems are thought to be secondary to weight loss. Some aspects of serotonin function do remain abnormal after weight restoration, suggesting that other mechanisms are involved.\textsuperscript{25,26} Another molecular genetic target of study is brain-derived neurotrophic factor (BDNF), which is also being studied in disease states such as depression.\textsuperscript{27}

Strong genetic influences are present in anorexia and likely play a role in both bulimia and BED, independent of the presence of obesity.\textsuperscript{28} Twin studies have shown concordance of ~55% and 35% in monozygotic twins and 5% and 30% in dizygotic twins for anorexia and bulimia, respectively. Genetic mutation studies have focused on polymorphisms of the serotonin 2A receptor, with mixed preliminary results.\textsuperscript{24} One acquired hereditary abnormality being studied is the presence of low-function alleles associated with the serotonin transporter (5-HTTLPR) and serotonin 2A receptor gene (~1438G/A), as findings suggest an association with poor treatment response.\textsuperscript{29}

Emphasis is also placed on social stress and psychological and developmental issues related to dysfunctional family relationships triggering abnormal eating behavior.\textsuperscript{4,7,18,20} Athletes are at risk for eating disorders, especially female gymnasts, ballet dancers, figure skaters, distance runners, swimmers, male wrestlers, and body builders.\textsuperscript{31}

**DIAGNOSTIC CRITERIA AND CLINICAL PRESENTATION**

Anorexia and bulimia occur together in ~30% to 64% of patients with eating disorders and may not be distinct diagnostic entities, but rather a continuum of symptoms. Thus, careful medical and psychiatric assessment at baseline is essential.\textsuperscript{12-24} Many patients initially present with either anorexia or bulimia and alternate from one to the other. Figure 73–1 demonstrates similar and unique features of both disorders.

### FIGURE 73–1. Signs and symptoms of anorexia nervosa and bulimia nervosa. (DST, dexamethasone suppression test; ECG, electrocardiogram.)
The use of purging methods is not limited to bulimia. Self-induced vomiting is the most common form of purging behavior.\(^{35}\) Laxative abuse is another form common in both anorexia and bulimia, used by an estimated 3% to 70% of patients.\(^{35-37}\) Although ineffective as a weight-loss strategy, laxative abuse is often used in combination with other behaviors, including exercise, diuretics, enemas, and saunas. Within the diagnostic framework of anorexia, laxative abuse is most common in those identified with the purging subtype.\(^{35}\) Psychiatric symptoms of depression, anxiety, and borderline personality disorder are also reported in those who abuse laxatives.\(^{35-37}\)

Depression, schizophrenia, obsessive-compulsive disorder (OCD), and conversion disorders should be included in the differential diagnosis of anorexia and bulimia, as eating abnormalities can be a component of these illnesses. The salient differences are the overriding drive for thinness, disturbed body image, increased energy directed at losing weight, and binge eating episodes that are relatively specific for eating disorders. Most patients with eating disorders experience relief of psychiatric symptoms on refeeding.\(^{19}\)

**ANOREXIA NERVOSA**

The core features of anorexia are refusal to maintain a minimal normal body weight (e.g., greater than 85% normal body weight or body mass index [BMI] greater than 17.5 kg/m\(^2\)) and failure to make expected weight gains, intense fear and obsession about weight gain or being “fat,” distorted body image, and amenorrhea for at least three consecutive cycles. Patients typically lack an appreciation for the degree of weight loss experienced or are preoccupied with the idea that a part of their body is too large, despite evidence to the contrary. The \textit{DSM-IV-TR} further classifies anorexia nervosa as restricting type (failure to engage in binge eating or purging behavior) or binge eating/purging type, in which patients regularly participate in bingeing or purging.\(^{35}\)

The anorexic patient has difficulty sensing when he or she is full (satiety) and commonly complains of feeling bloated after eating. Patients also describe not feeling in control of various aspects of their life, particularly caloric intake. Anorexic patients often present with features of major depression, but these symptoms should initially be considered to be secondary to starvation and not a true mood disorder.

Several proposed changes for the not yet released fifth edition of \textit{Diagnostic and Statistical Manual of Mental Disorders} are being considered. These include the potential elimination of the amenorrhea diagnostic component and elimination of the subclassifications of anorexia nervosa.\(^{36}\)

**CLINICAL PRESENTATION OF ANOREXIA NERVOSA**

**General**
- Patients refuse to maintain body weight and have distorted perceptions about their body.

**Symptoms**
- Patients have obsessions and fears about eating and gaining weight.
- They complain about feeling full even when they have eaten very little food.
- Denial of symptoms and low self-esteem are the norm. Patients often feel ineffective and have a lack of self-control.

**Signs**
- Weakness, lethargy, cachexia, amenorrhea, vomiting, restricted food intake, inappropriate exercise, delayed sexual development, edema, delayed gastric emptying, constipation, bradycardia, hypotension, osteoporosis, dry cracking skin, lanugo, callus on dorsum of hand, perioral dermatitis, erosion of dental enamel

**Laboratory Abnormalities**
- Hypokalemia, hypokalemic alkalosis, hypomagnesemia, leukopenia, QT interval prolongation, ST segment depression, U waves, hypercholesterolemia, anemia

**Other Diagnostic Tests**
- Nonspecific electroencephalogram (EEG) changes

**BULIMIA NERVOSA**

The core feature of bulimia nervosa is recurrent episodes of binge eating (an excessive intake of calorie-laden food over a short period of time). Persons with bulimia are overly sensitive about their weight and have a distorted body image. Most have normal weight, although they might fluctuate between being underweight and overweight. Patients lack control over their eating and participate in recurrent compensatory behavior to prevent weight gain. These behaviors may include self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; strict dieting or fasting; or excessive exercise. To meet \textit{DSM-IV-TR} criteria, the binges and compensatory behaviors must occur on average at least twice weekly for 3 months. Bulimia can further be differentiated by purging type (regularly engages in self-induced vomiting or the misuse of laxatives, diuretics, or enemas) or nonpurging type (uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but does not engage in purging activities).\(^{35}\)

**CLINICAL PRESENTATION OF BULIMIA NERVOSA**

**General**
- Patients binge eat and stop when they have abdominal pain or self-induced vomiting or are interrupted by another person.
Psychiatric Disorders

They have a pattern of severe dieting followed by binge eating episodes.

They are concerned about their body image but do not have the drive to thinness, which is characteristic of anorexia nervosa.

### Symptoms

- Patients do not eat regular meals and do not feel satiety at the end of a meal.
- They may use laxatives for weight control.
- They have guilt, depression, and self-disparagement after binges.
- Social isolation can result from frequent bingeing.
- Chaotic and troubled personal relationships and substance abuse are common.

### Signs

- Bingeing, vomiting, salivary gland inflammation, erosion of dental enamel, callus on dorsum of hand, perioral dermatitis, dental caries, parotid gland enlargement, abdominal pain, upper end of normal body weight or slightly overweight, frequent weight fluctuations, diminished masticatory ability

### Laboratory Abnormalities

- Hypokalemia, hypochloremic metabolic acidosis, elevated serum amylase

### Other Diagnostic Tests

- None

Under consideration for DSM-V is the potential standardization of the frequency of symptoms for bulimia and BED by reducing the requirement from two to one time per week for 3 consecutive months and also eliminating the subclassifications of bulimia nervosa.  

### CLINICAL CONTROVERSY

Bulimia nervosa involves extensive binging and purging behaviors. New diagnostic considerations are being considered for DSM-V which would reduce the frequency of binging episodes necessary to establish the diagnosis of bulimia nervosa.  

Patients typically binge and vomit at least once daily. Caloric intake varies, but patients can consume between 5,000 and 20,000 calories (20,929 and 83,716 J) during a single binge. Patients tend to consume foods that are easy to ingest, do not require much chewing or preparation, and are high in carbohydrates or fat. Binge eating is typically secretive and precipitated by a stressful event, followed by postbinge remorse. Binges often last less than 2 hours but can extend to more than 8 hours. To compensate for the excessive caloric intake, many patients fast for prolonged periods, exercise compulsively, purge, or abuse laxatives.

Psychiatric comorbidity includes depression (up to 80%), poor impulse control, and substance abuse. Approximately 30% to 37% of bulimic patients have a personal history of substance abuse. Kleptomania and borderline and avoidant personality disorders are also frequently observed. Patients also commonly steal laxatives and comfort items, such as candies and clothes.

### BINGE EATING DISORDER

Patients with binge eating disorder present with recurrent episodes of binging without the compensatory behaviors associated with anorexia or bulimia. It is estimated that 5% to 10% of patients seeking treatment for obesity have BED. Comorbid psychotic disorders are common and reported in >70% of BED patients. Major depressive disorder and low self-esteem are common, although the self-deprecating focus on body image is less severe than in anorexia or bulimia.

Diagnostic criteria require that episodes of binging occur at least twice weekly over a period of 6 months.

For the DSM-V, there may be standardization of frequency and time frame for compensatory behaviors as well as adding BED as a formal diagnosis.

### MEDICAL COMPLICATIONS OF EATING DISORDERS

The potential medical complications of eating disorders involve multiple organ systems. The type of medical complication encountered is dependent on the type and frequency of the eating disorder behavior. Cardiac complications may occur and can include wasted cardiac muscle, orthostatic hypotension, decreased cardiac output, arrhythmia, and QTc interval prolongation. During caloric restoration, there is a potential risk for developing fatal cardiovascular collapse known as refeeding syndrome. This risk is reduced by the gradual versus rapid reintroduction of calories.

Metabolic (metabolic acidosis, metabolic alkalosis) and electrolyte disturbances (e.g., hypokalemia, hypomagnesemia, and hypocalcemia), and dehydration are often seen. Elevations in bicarbonate levels during periods of hypokalemia can be an indication that the patient is inducing vomiting or using dietary weight loss medications. Non-anion-gap acidosis has also been reported with the abuse of laxative agents. Additionally, both acute and chronic renal failure has been reported.

Gastrointestinal (GI), oropharyngeal, and dental complications are frequent, as are general complaints of lethargy and fatigue.

Hormonal changes related to the hypothalamic-pituitary-gonadal axis resulting from starvation are seen. These abnormalities include effects on estradiol, the gonadotropins (e.g., luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing hormone), thyroid function, adrenal function, and growth hormone. Specific to female athletes is the female athlete triad, defined by the development of irregular menses, osteoporosis, and disordered eating.

Osteopenia, osteoporosis, and infertility are potential long-term complications of suppressed estrogen. The restoration of weight, specifically in anorexia nervosa, reverses the bone loss, although estrogen supplementation does not appear to be effective. In all cases, the preferred method to address these issues is the normalization of nutrition. The impact on female fertility is not well studied, although the ability to carry a pregnancy to term or to give birth to a child of average birth weight appears reduced.

Chronic starvation can contribute to brain atrophy. Decreases in white matter and cerebrospinal fluid volumes return to normal after a healthy weight is achieved, but gray matter loss can persist. A thorough physical and laboratory evaluation, as described in Table 73–1, is essential to determine the severity of medical complications.

body image; restore and maintain healthy body weight; establish

normal eating patterns; improve psychologic, psychosocial, and

physical problems; resolve contributory family problems; enhance

compliance; and prevent relapse.55 Specific to BED is the additional

goal of weight loss.

ANOREXIA NERVOSA

The long-term prognosis of patients with anorexia nervosa is not clear, as studies focus only on patients receiving treatment. The course of the disorder most commonly consists of a single episode with subsequent return to normal weight, although patients can still experience issues with disturbed body image, disordered eating, and other psychiatric problems.52 Some patients experience an unremitting course leading to death, whereas others suffer episodically. It is estimated that less than 50% of anorexic patients recover, and 20% remain chronically ill despite weight normalization, return of men-

ses, and improved eating behaviors.52 The prognosis is more favor-

able with longer follow-up care and younger age of onset, whereas

a poorer prognosis is associated with chronic illness, lower initial

weight, poor family relationships, obsessive-compulsive personality

symptoms, and the presence of bulimia or purging behavior.24,52–54

Long-term follow-up shows high mortality rates, with 5% to 10%
of anorexic patients dying, most often the result of cardiac arrest or

suicide.16,52

Table 73–2 is and is limited to only the most severely ill patients.24,30,31 Medications are rarely indicated as a sole treat-

ment for eating disorders, and many patients refuse medication, although they remain part of the comprehensive treatment strat-

gy.55–57 Comparative, double-blind, placebo-controlled trials are

sparse, and most are limited by small sample sizes, ambivalent

patient attitudes toward treatment, medical complications, and high dropout rates.58

Psychiatric Disorders

ANOREXIA NERVOSA

Nonpharmacologic Treatments

CLINICAL CONTROVERSY

Cognitive behavioral therapy and other nonpharmacologic interventions are generally considered preferred first-line treatment options for anorexia nervosa. Controversy exists as to what level of symptomatology should be present to consider the initiation of pharmacologic therapy.

Evidence supports that nonpharmacologic treatments have the greatest likelihood of eliciting a response in anorexic patients. This includes CBT, behavioral management, interpersonal psychotherapy, nutritional counseling, and family therapy. Current guidelines suggest at least 6 months of psychotherapy. CBT helps the patient overcome distorted thinking, including self-worth as measured by body image, feelings of being fat despite evidence to the contrary, and denial. CBT also teaches patients how to use strategies besides eating to cope. Interpersonal psychotherapy focuses on interpersonal relationships and functioning, whereas CBT provides positive reinforcement for weight gain. The benefit of treatment based on an addiction model (12-step program) is not supported by the literature. Many psychiatric symptoms in an acutely ill patient, such as depression and anxiety, diminish or disappear with weight restoration. Initial treatment is directed toward restoring a healthy weight (greater than 90% of normal weight for age-matched controls) and treating food phobias. After achieving medical stability and appropriate weight, therapy can be redirected toward addressing ongoing interpersonal problems, weight maintenance, cognitive restructuring, and skill development for relapse prevention. Oral refeeding, initially with liquid formulas if necessary, is the most common approach to weight restoration. In severe cases, nasogastric refeeding is preferred over intravenous (IV) bolus dosing. Total parenteral nutrition is reserved only for the management of severely malnourished patients and if other refeeding methods fail. The decision to administer total parenteral nutrition must be made carefully, because of the potentially devastating psychologic effect on patients who do not wish to gain weight. Current clinical evidence suggests a controlled weight gain of 0.9 to 1.4 kg (2–3 lb) per week in inpatient settings and 0.2 to 0.5 kg (0.5–1 lb) per week in outpatient settings. Recommendations vary; however, it is considered acceptable for patients to begin refeeding at 1,000 to 1,600 calories per day (4186 to 6697 J/day) (30–40 cal/kg/day [126–167 J/kg]) with slow titration upwards until they begin to demonstrate sustained weight gain. This can require the intake of an additional 3,500 to 7,000 extra calories (14,650 to 29,301 J) per week. Slow refeeding is important to minimize the risk of medical and psychologic consequences.

Pharmacologic Therapy

Antidepressants

Although many studies examine the role of antidepressants in the treatment of anorexia nervosa, they often have small sample sizes and large confidence intervals. Antidepressants currently have no role in the acute treatment of anorexia, unless there is another clinical indication present. Data suggest that medication is ineffective if a patient weighs less than 85% of his or her expected weight. Thus, antidepressants should be initiated only if depression, anxiety, obsessions, or compulsions persist after the target weight is achieved. The duration of treatment when antidepressants are used in this manner is unclear, but one study showed benefit in treated patients for 1 year, and current guidelines suggest 9 to 12 months of therapy. Antidepressants, along with psychotherapy, have been used to help maintain weight and prevent relapse, but data supporting this are limited. Most clinicians prefer the selective serotonin reuptake inhibitor (SSRI) antidepressants because they are better tolerated and have greater cardiovascular safety than tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). Because these patients are sensitive to anticholinergic and cardiovascular effects, if TCAs or MAOIs are used, low starting doses and slow titration toward an effective dose are appropriate. The risk of cardiotoxicity in a malnourished population must not be underestimated, and a baseline electrocardiogram (ECG) should be obtained before initiation of these agents. Fluoxetine continues to be the most widely studied SSRI in anorexia. Most clinicians initiate at low doses, for example, 20 mg/day, and increase to a maximum of 60 mg/day based on response and tolerability. Some clinical controversy exists regarding when antidepressant therapy should be initiated. During the starvation phases of anorexia, the majority of clinical trials suggest antidepressants are ineffective, and there is debate as to their effectiveness once weight restoration has occurred. Evidence from a 52-week, randomized, placebo-controlled clinical trial of 93 patients with the treatment arm receiving doses from 20 to 80 mg/day showed no difference between fluoxetine and placebo for time to relapse. Antipsychotics

Typical antipsychotics were the first medications used to treat anorexia to reduce obsessive and paranoid thoughts about weight gain and anxiety and to promote weight gain. However, there was little improvement, and the risks were considered to outweigh the benefits. Atypical antipsychotics have provided an additional alternative for treating anorexia. Most of the data are from case reports or small trials in both adolescents and adults using risperidone 0.5 to 1.5 mg daily, olanzapine 2.5 to 15 mg daily, and quetiapine 200 to 500 mg daily. Improvement has been shown through weight increase and reduction of comorbid anxiety and depressive symptoms, but not all reports are favorable, and these agents require further study. Caution is urged in view of the report of increased QTc in an anorexic patient taking risperidone. Optimal treatment duration is unknown, as most of the larger studies are less than or equal to 3 months in duration.

Miscellaneous Agents

Metoclopramide can be helpful in reducing bloating, early satiety, and abdominal pain commonly found in anorexia, but it does not affect weight gain. Low-dose, short-acting benzodiazepines (0.25 mg alprazolam or 0.5 mg lorazepam) given before meals are useful when severe anxiety limits eating. Estrogen replacement has been used, but restoring menses through refeeding is a preferred approach to minimize bone density loss.

BULIMIA NERVOSA

Nonpharmacologic Therapy

The nondrug strategies used in bulimia are similar to those used with anorexia, and they are equally critical to success. CBT has the strongest evidence supporting its benefit in managing bulimia. Current treatment guidelines suggest that CBT should consist of 16 to 20 sessions over a 4- to 5-month period. Interpersonal psychotherapy also plays a role and has a moderate degree of evidence to support its use. Nutritional counseling, planned meals, and self-monitoring can help interrupt the binge–purge cycle. Family therapy in bulimic patients is less critical than with anorexia, as these patients tend to be older. A recent study suggested that CBT-guided self-care was a more effective treatment approach in adolescents than family therapy, whereas other programs using self-help guides based on CBT have shown mixed results.

When such programs have been combined with medication, for example fluoxetine,
enhanced response has been reported.\textsuperscript{77,78} Data support the use of 12-step programs, but they should not be used as monotherapy.\textsuperscript{16,24}

**Pharmacologic Therapy**

**Antidepressants** Antidepressants are used in the acute and maintenance phases of bulimia adjunctively with nonpharmacologic approaches. A wide array of antidepressants, including TCAs, MAOIs, trazodone, serotonin-norepinephrine reuptake inhibitors (SNRIs), and SSRIs, have been studied. Additionally, several reviews analyzing this body of literature have been published, although there continues to be limited placebo-controlled, randomized, double-blind clinical studies.\textsuperscript{24,35} Antidepressants are reported to reduce depression, anxiety, obsessions, and impulsive behaviors such as binge eating and purging, and improve eating habits, although their impact on body dissatisfaction remains unclear. The presence of comorbid mood disorders is not necessary for an antidepressant response.\textsuperscript{24,79,80}

The benefit appears to be more robust in the acute phase of the illness, as relapse despite continued antidepressant use is common in patients who are in or near remission.\textsuperscript{24,30,57} Antidepressant response usually occurs in 6 to 8 weeks, and reduction in frequency of binge–purge behavior has been as high as 73\% and as low as 30\%.\textsuperscript{56} Abstinence rates (elimination of bingeing and purging behaviors) with short-term use range from zero to 68\%. More data are needed to determine the long-term benefits of antidepressants for preventing relapse of bulimia symptoms. One trial evaluating the impact of fluoxetine versus placebo in the maintenance phase showed a better outcome in patients receiving fluoxetine 60 mg/day, although high dropout rates in both groups blurred the overall benefit.\textsuperscript{81}

SSRIs are the preferred agents because of their tolerability and because they have been studied in the largest number of patients. Fluoxetine remains the only medication with Food and Drug Administration (FDA) approval for bulimia. Tolerability is the primary criterion for selecting an antidepressant in the treatment of bulimia because of patients’ heightened sensitivity to adverse effects and the lack of a clear difference in efficacy between the classes. Even though there is a suggestion that MAOIs produce the most robust effect, the risk of using these medications in impulsive patients limits their use.\textsuperscript{85} SNRIs have shown promising results; however, the data supporting their use are limited to case reports.\textsuperscript{85} Bupropion is not used in bulimic patients because of the increased risk of seizures.

Before initiating pharmacologic-based therapy, a careful baseline physical examination, ECG, and laboratory work-up are essential. Underlying ECG changes secondary to hypokalemia or bradycardia and atioventricular block from starvation can be present. There is potential for fatal outcomes secondary to cardiac arrest or suicide. All antidepressants can cause seizures; thus, a careful risk–benefit assessment is warranted if the patient has predisposing factors such as a personal or family history of seizures, cerebrovascular disease, or alcohol or sedative-hypnotic withdrawal.

Doses in the treatment of bulimia nervosa are similar to those in patients treated for depression, though at the higher end of the range. Readers are referred to Chapter 78 for antidepressant dosing ranges. For fluoxetine, the higher end of the dosing range, 60 mg/day, can be necessary for response.\textsuperscript{83} With other agents, most clinicians initially target the bottom of the middle of the dosing range and increase the dose if there is an inadequate response. Slow titration is needed to allow time to develop tolerance to adverse effects. If TCAs are used, serum concentration monitoring is recommended to ensure that absorption is not compromised by purging.

The time for antidepressant onset of effect in bulimia is unclear. In the absence of data, the definition of a therapeutic trial from the depression literature (4–8 weeks at a therapeutic dose) should be used. Because the majority of subjects will not experience a complete remission, and there are few data on predictors of response or whether switching to another class will improve response, a clear and specific target should be stated initially.\textsuperscript{14}

**CLINICAL CONTROVERSY**

Antidepressant therapy is the preferred treatment intervention for bulimia nervosa, however it is unclear whether long-term pharmacologic treatment reduces the risk of relapse compared to shorter duration treatment interventions of a year or less.

The evidence is mixed as to whether any early benefit is sustained; hence, the decision to continue treatment should be made based on both initial response and the maintenance of that benefit. If the symptoms return within a few months after antidepressant discontinuation, then the treatment might need to be reinitiated.

**Mood Stabilizers (Lithium and Anticonvulsants)** Because of the lack of evidence demonstrating their benefit, lithium and anticonvulsants are reserved for bulimic patients with a comorbid bipolar affective disorder.\textsuperscript{19,84} Target serum concentrations and doses are similar to those used for patients with seizure or mood disorders. Lithium must be used cautiously, as fluid shifts related to purging and laxative abuse increase the risk of toxicity. The adverse effect of weight gain often makes mood stabilizers and anticonvulsants unacceptable to patients in the long term.

**Miscellaneous Agents** Low-dose benzodiazepines before meals can help reduce anxiety associated with refeeding, although long-term use is not warranted because of the risk of abuse and dependence. One double-blind trial with ondansetron has shown benefit, but there are insufficient data to recommend a specific role for this agent.\textsuperscript{86} Antipsychotics and appetite suppressants do not play a role in managing central symptoms of bulimia.\textsuperscript{24}

**Nonpharmacologic versus Pharmacologic Approaches**

The combination of pharmacologic and nonpharmacologic measures appears to produce the best chance for a positive outcome for patients with bulimia nervosa.\textsuperscript{79} Antidepressants, specifically SSRIs, are the class of choice in bulimic patients, whereas other medications are reserved for patients with comorbid psychiatric conditions. Only in unusual circumstances should patients be treated with antidepressants alone. Evidence suggests the greatest benefit is during the acute phase of treatment, whereas data are mixed supporting their role in the prevention of relapse.

**BINGE EATING DISORDER**

As in anorexia and bulimia, CBT and interpersonal psychotherapy seem to be the most effective interventions.\textsuperscript{71} Antidepressants, anticonvulsants, and appetite suppressants are the pharmacologic agents with the greatest promise in BED, but data are limited, trials are short in duration (20 weeks or less), and whether there is sustained benefit is unclear.\textsuperscript{86} Although reports are mixed, antidepressants have demonstrated efficacy as monotherapy at reducing binge eating and improving depressed mood during the acute phases of
In summary, the question of where BED fits on the diagnostic spectrum continues to be explored. Current literature suggests that three different types of pharmacologic agents (SSRIs, topiramate, and sibutramine) hold promise in the short term, but long-term data are lacking. As with other eating disorders, nonpharmacologic treatments are the key to a successful outcome.

PHARMACOECONOMIC CONSIDERATIONS

There are no formal evaluations of the economic impact of eating disorders on individual patients, on global healthcare costs, or on indirect costs such as unemployment, premature death, or disability payments. The chronic course, severe disability, and lack of...

FIGURE 73-2. Bulimia nervosa treatment algorithm. (CBT, cognitive behavioral therapy; IPT, interpersonal psychotherapy; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.)
improvement in up to one-third of patients suggest a significant cost impact. Clinicians should contribute to the appropriate use of resources by ensuring that medications are used in situations in which there is evidence demonstrating their benefit and that they are never used as the sole treatment modality. For example, antidepressants are started after normal weight is restored in anorexic patients and not to treat depressive symptoms in significantly malnourished patients. One study evaluating the relative costs of CBT alone, medication alone, or combination treatment in bulimia concluded that if overall effectiveness was the prime consideration, then CBT, with medication added if the response was inadequate, was the best approach. If cost-effectiveness was the basis for making treatment decisions, then antidepressants alone as a first step, followed by the addition of CBT when response is inadequate, is the preferred next intervention.92

EVALUATION OF THERAPEUTIC OUTCOMES

ANOREXIA NERVOSA

A combination of subjective and objective measures is used to assess patient response. A reduction in the frequency and severity of abnormal eating habits, normalized exercise patterns and laboratory tests, and a sustained weight close to age-matched normals are key indicators of response. A diary recording exercise frequency, menses, food intake, patterns of eating, and associated feelings while eating is a useful tool to track progress, especially in the outpatient setting. Weekly weigh-ins on the same scale, preferably at a clinician’s office, help monitor progress early in treatment and reduce the focus on weight and anxiety caused by the variability found among different scales. Follow-up laboratory tests and ECGs are not part of routine monitoring unless the patient is restricting food intake, is purging, or continues to lose weight despite treatment. Inpatients require daily assessment of weight and caloric intake, vital signs, and urine output because of the more severe nature of their illness. They also can need monitoring of bathroom privileges early in their care. A healthy weight gain of no more than 0.2 to 0.5 kg (0.4 to 1.1 lb) per week toward a goal of 90% to 95% of normal weight or a BMI greater than 18.5 kg/m² is a critical sign of treatment success. A patient’s use of coping skills and contingencies for dealing with stress other than manipulating food consumption also should be assessed. Antidepressants can assist in alleviation of persistent depression, anxiety, and obsessions, after weight restoration. Improvement in mood is expected to occur within 8 weeks. Patients receiving TCAs should be evaluated for dry mouth, constipation, hypotension, and sedation. Patients receiving SSRIs should be monitored for agitation, drug-induced anorexia, nausea, weight loss, and insomnia. The decision to use long-term medication must be based on specific and sustained improvement in the target symptoms, balanced against adverse effects.

BULIMIA NERVOSA

An individualized treatment and monitoring plan begins with a thorough assessment describing the baseline frequency and severity of treatment-responsive target symptoms and other associated findings. The assessment must be comprehensive, as a patient can hide his or her illness by shifting from one type of behavior to another (e.g., exercise to purging).

A comprehensive assessment includes a description of psychiatric symptoms, physical findings, frequency and severity of binge–purge episodes, laxative and ipecac use, exercise patterns, and laboratory and ECG abnormalities. Interpersonal and relationship problems should also be evaluated. Some findings indicating a more chronic course of illness, such as salivary gland inflammation and erosion of dental enamel, can take months to reverse or might never normalize. Hence, these are not sensitive indicators of early treatment response. Data describing a patient’s baseline level of functioning and previous response to treatment should be used to set goals in the current treatment plan.

Antidepressant response usually occurs within 4 to 8 weeks after the onset of treatment. If response does not occur, binge–purge behavior should be considered as a factor potentially contributing to the malabsorption of medication. If this behavior is not present, then every attempt should be made to maximize the dose. Serum concentration monitoring, when appropriate as with TCAs, should be done periodically (every 3–6 months if a patient is responding and tolerating the medication, or more frequently if clinically indicated). Evaluation of previously described adverse effects also should be part of the monitoring plan. If the patient responds, he or she should be followed for 6 to 12 months, then reassessed for the need for ongoing medication. If the patient relapses on medication discontinuation, then the medication should be restarted.

Ambulatory eating disorder patients present a particular challenge to clinicians. Impulsivity associated with bulimia nervosa can increase the risk for suicide. Prescriptions should be limited to small supplies. In addition, pharmacists should be alert to persons who make large or frequent purchases of laxatives or ipecac syrup, as this is an indicator of possible bulimic behaviors.

CONCLUSION

Our understanding of the pathophysiology and symptomatology of eating disorders has improved significantly over the past several years. Medication serves an adjunctive role to a variety of psycho-social therapies in anorexia nervosa, whereas it plays a more central role in bulimia nervosa and BED treatment. By gaining a greater understanding of the underlying physiologic changes and the psychosocial complications associated with eating disorders, treatment plans can be specifically designed for an individual patient with the goal of improving his or her quality of life.

REFERENCES

Since publication of the last edition of this textbook, a disturbing trend in drug abuse has continued: the use of medicinal drugs for nonmedicinal purposes. Between 1995 and 2002 there was a 163% increase in the number of emergency room visits tied to the abuse of prescription drugs, and these percentages continue to increase. Prescription drugs now are a factor in one fourth of all overdose deaths reported in the United States. Central nervous system (CNS) agents, primarily analgesics (pain relievers), were involved in slightly less than one half (47%) of all drug-related suicide attempts that presented to emergency departments in 2005, including both prescription and over-the-counter (OTC) formulations. More than 56% of suicide-related emergency department visits included psychotherapeutic agents (e.g., benzodiazepines or antidepressants).

This chapter and the next focus on the problems associated with the abuse of chemical substances and what clinicians can do to help deal with these problems.

**KEY DEFINITIONS**

The lack of a common vocabulary in substance abuse treatment and prevention leads to several problems. Wide arrays of terms are in common use, many without precise meaning. This lack of universal agreement on language hampers effective communication among professionals and leads to difficulties in formulating public policy and administering third-party reimbursement programs. The Liaison Committee on Pain and Addiction, a collaborative effort of the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine has developed definitions related to the use of medications for the treatment of pain consistent with current understanding of relevant neurobiology, pharmacology, and appropriate clinical practice. The definitions have been approved by each of the three collaborating organizations. The following definitions resulted from this consensus development committee.

- **Addiction** is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following 5Cs: chronicity, impaired control over drug use, compulsive use, continued use despite harm, and craving.

- **Drug abuse** is a maladaptive pattern of substance use characterized by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use creating physical danger, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.
Physical dependence is a state of adaptation that is manifested by a drug-class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

Tolerance is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug’s effects over time.

**EPIEDEMOLOGY**

**NATIONAL SURVEY ON DRUG USE AND HEALTH**

The National Survey on Drug Use and Health (NSDUH) is the primary source of statistical information on the use of illegal drugs by the U.S. population. Conducted by the federal government since 1971, the survey collects data from a representative sample of the population at their place of residence.

In 2008, the survey found that an estimated 20.1 million Americans aged 12 or older were current illicit drug users, meaning they had used an illicit drug during the month prior to the survey interview. An estimated 22.2 million Americans suffered from substance dependence or abuse because of drugs, alcohol, or both. The 2008 survey found that marijuana was the most commonly used illicit drug (15.2 million past month users). About 6.2 million Americans—2.5% of the population—said they abused prescription drugs in the past month in 2008, a decrease from 2.8% of the population in 2007, but still a monumental problem in our country.

**MONITORING THE FUTURE STUDY**

Every year the Institute for Social Research at the University of Michigan conducts its Monitoring the Future Study, supported under a series of research grants from the National Institute on Drug Abuse. A main purpose of this research is to study changes in the beliefs, attitudes, and behavior of young people in the United States.

In 2009, 46,097 U.S. students in 8th, 10th, and 12th grades in 389 public and private secondary schools were surveyed. Findings show that smoking marijuana is gaining popularity among U.S. teens, even though they have cut down on smoking cigarettes, binge drinking, and using methamphetamine. Researchers postulate that the increase of smoking marijuana is partly attributable to the national debate over the medical use of cannabis which may make the drugs seem safer to teenagers. In addition to marijuana, fewer teens also view prescription drugs and Ecstasy as dangerous, which may explain why more teens also are abusing prescription pain pills and attention-deficit drugs.

Illicit or street drug use has shown considerable declines over the past decade or so, perhaps indicating a shift toward abuse of other prescription drugs. These include sedatives, tranquilizers, and narcotic drugs other than heroin (most of which are analgesics). As a result, they have become a much more important part of the nation’s drug abuse problem.

**SUBSTANCE ABUSE EMERGENCIES: THE DAWN PROGRAM**

Since the early 1970s, the Drug Abuse Warning Network (DAWN), has collected information on patients seeking hospital emergency department treatment related to their use of an illegal drug or the nonmedical use of a legal drug. These data allow healthcare professionals to be better prepared to react to medical emergencies arising from illegal drug use and to target prevention and education programs to specific drug-using groups or populations.

Unfortunately, there is about a 2-year lag in the occurrences of ED visits and publication of the data and a limited number of metropolitan areas is surveyed.

DAWN defines a drug-related episode as an ED visit that was induced by or related to the use of an illegal drug(s) or the nonmedical use of a legal drug for patients aged 6 to 97 years. In 2006, hospitals in the United States delivered a total of 113 million ED visits, and DAWN estimates that 1,742,887 ED visits were associated with drug misuse or abuse. Of those ED visits, some key findings include the following:

- 31% involved illicit drugs only
- 28% involved pharmaceuticals only
- 7% involved alcohol only in patients under the age of 21
- 13% involved illicit drugs with alcohol
- 10% involved alcohol with pharmaceuticals
- 8% involved illicit drugs with pharmaceuticals
- 3% involved illicit drugs with pharmaceuticals and alcohol

**ECONOMIC IMPACT OF SUBSTANCE ABUSE**

Substance abuse and addiction have an enormous impact on the economy. Over the years, the National Center on Addiction and Substance Abuse (CASA) at Columbia University has conducted studies aimed at quantifying the costs to local, state, and federal governments and agencies. The most recent figures are based on 2005 spending because that was the most recent year for which data were available over the course of the latest study.

As noted earlier, substance abuse and addiction cost federal, state, and local governments at least $467.7 billion in 2005. The CASA report found that of $373.9 billion in federal and state spending, 95.6% ($357.4 billion) went to “shovel up the consequences and human wreckage of substance abuse and addiction”; only 1.9% went to prevention and treatment, 0.4% to research, 1.4% to taxation and regulation, and 0.7% to interdiction.

Of the $3.3 trillion total federal and state government spending, $373.9 billion—11.2%, more than $1 of every $10—was spent on tobacco, alcohol, illegal, and prescription drug abuse, addiction, and its consequences.

For every $100 spent by state governments on substance abuse and addiction, the average spent on prevention, treatment, and research was $2.38. For each dollar in alcohol and tobacco taxes and liquor store revenues that federal and state governments collect, they spend $8.95 dealing with the consequences of substance abuse and addiction.

**ACUTE VERSUS CHRONIC PROBLEMS**

1. Misuse of chemical substances causes problems of two types: those that occur acutely and those that arise after continued use of a drug. Acute problems are usually predictable, given the pharmacology of the drug. Chronic abuse of chemical substances can cause a wide array of physical, psychological, and psychiatric morbidities. The substance-induced disorders discussed here mainly include intoxication and withdrawal.

1. The essential feature of substance dependence is the continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug. Patients who take prescribed drugs for appropriate medical indications and in correct doses may still show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than being tapered. Tolerance and physical dependence are
inevitable consequences of chronic treatment with opioids and certain other drugs, but by themselves, tolerance and physical dependence do not imply “addiction.” To meet Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) criteria for the diagnosis of substance dependence, at least three of the following must be present at any time in a 12-month period:

1. Tolerance
2. Withdrawal, indicated by the appearance of the characteristic withdrawal syndrome or the use of the same or related drug to relieve or avoid withdrawal symptoms
3. Substance is taken in larger amounts or over a longer period of time than was intended
4. Patient has a persistent desire or unsuccessful efforts to cut down or control substance use
5. Considerable time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects
6. Social, occupational, or recreational activities are given up or reduced because of substance use
7. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychologic problem caused or exacerbated by the substance

In 2008, an estimated 22.2 million persons (8.9% of the population aged 12 or older) were classified with substance dependence or abuse in the past year based on these criteria. Of these, 3.1 million were classified with dependence on or abuse of both alcohol and illicit drugs, 3.9 million were dependent on or abused illicit drugs but not alcohol, and 15.2 million were dependent on or abused alcohol but not illicit drugs.

The characteristic feature of substance abuse is a maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights. Intoxication refers to the development of a substance-specific syndrome after recent ingestion and presence in the body of a substance, and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the CNS. Examples include belligerence, mood lability, impaired judgment, and impaired social or occupational functioning. Evidence for recent intake of the substance can be obtained from the history, physical examination, or laboratory examination. The most common changes involve disturbances in perception, wakefulness, attention, thinking, judgment, motor behavior, and interpersonal behavior.

As with most illnesses, the course and prognosis of the disorders of substance use and dependence are variable. Untreated physical withdrawal from CNS depressants is potentially life-threatening, but withdrawal almost always can be managed successfully with proper medical care. Getting patients who are drug dependent to stop using drugs is very difficult, and many patients return to drug use even after treatment. As many as 75% of treated, substance-dependent patients will relapse at least once. Many patients, however, are able to obtain recovery with treatment and continued care in 12-step programs such as Alcoholics Anonymous or Narcotics Anonymous. Substance dependence or addiction can be viewed as a chronic illness that can be controlled successfully with treatment but cannot be cured and is associated with a high relapse rate. Without treatment, the course can progress to life-threatening severity, resulting from the effects of the drug, drug contaminants, or medical complications of use. Recently, the definitions used in the DSM-IV-TR criteria have been criticized. Although an in-depth discussion of the mechanism of drug addiction is beyond the scope of this chapter, the interested reader is directed to a review article that presents the current understanding of the biology of drug addiction.

DIVERSION OF PHARMACEUTICAL CONTROLLED SUBSTANCES

The nonmedical or recreational use of pharmaceutical controlled substances has dramatically increased in the United States in recent years, although there has been a slight downward trend when comparing 2007 to 2008. About 6.2 million Americans—2.5% of the population—said they abused prescription drugs in the past month in 2008. An estimated 4.7 million persons used pain relievers nonmedically in the past month in 2008, 1.8 million used tranquilizers, 904,000 used stimulants, and 234,000 used sedatives.

In 2008 4.7 million teens reported they had abused a prescription drug at some time in their lives. Family medicine cabinets were cited as the main source for obtaining prescription drugs. About 4 out of 10 (41%) teens agree that prescription drugs are much safer to use than illegal drugs. Furthermore, the same study concluded that 31% believe there is “nothing wrong” with using prescription medicines without a prescription “once in awhile.” From a supply standpoint for the first time, this year researchers asked 12- to 17-year olds how fast they can get prescription drugs, and found that 19% of teens (4.7 million) can get prescription drugs (in order to get high) in an hour; 35% (8.7 million) can get prescription drugs within a day.

One of the main factors contributing to the nationwide increase in the diversion of pharmaceutical controlled substances has been the rise in the number of Internet sites that sell or facilitate the sale of these drugs for other than legitimate medical purposes. So-called “prescription mills” remain a major source of diversion. The advent of rogue websites that cater to those who abuse pharmaceutical controlled substances has allowed the criminal operators of these sites to exploit the anonymity of the Internet to generate illicit sales of controlled substances, including prescriptions to an extent far exceeding those of any in-person prescription mill. This is particularly evident when examining the data relating to the sales of hydrocodone, which is the most widely abused pharmaceutical controlled substance in the United States. According to data provided to the U.S. Drug Enforcement Administration (DEA) in 2006 by registered distributors of controlled substances, 34 U.S. pharmacies supplying rogue Internet sites dispensed more than 98 million dosage units of hydrocodone. Hence, these pharmacies each dispensed an average of approximately 2.9 million dosage units of hydrocodone per pharmacy in a single year. By means of comparison, the average pharmacy in the United States dispenses approximately 88,000 dosage units of hydrocodone per year.

For 5 years, CASA at Columbia University has been tracking the availability of controlled prescription drugs over the Internet. In an in-depth white paper on the subject of Internet diversion of prescription drugs, CASA referred to the Internet as a “Pharmaceutical Candy Store.” The disheartening results of this study helped Congress passed the Ryan Haight Act, federal legislation that, effective April 13, 2009, made it illegal under federal law to "deliver, distribute, or dispense a controlled substance by means of the Internet, except as authorized by [the Controlled Substances Act]."

CNS DEPRESSANTS

BENZODIAZEPINES AND OTHER SEDATIVE-HYPNOTICS

Emergency department visits involving benzodiazepines clearly outnumber those involving any of the other types of
Dependence on Sedative-Hypnotics

1116

Psychiatric Disorders

In clinical practice, the benzodiazepines largely have replaced the short-acting barbiturates and other nonbarbiturate sedative-hypnotics. Benzodiazepines with faster onset (e.g., diazepam) tend to be preferred by the recreational drug user because they are reinforcing. Flunitrazepam emerged in the mid-1990s as an illegal drug to be preferred by the recreational drug user because they are rein-

Withdrawal symptoms are tremor, tachycardia, diaphoresis, nausea, vomiting, elevated blood pressure, delirium, seizures, and hallucinations.

*Withdrawal symptoms are tremor, tachycardia, diaphoresis, nausea, vomiting, elevated blood pressure, delirium, seizures, and hallucinations.
γ-HYDROXYBUTYRATE

γ-Hydroxybutyrate (GHB) is a chemical compound structurally similar to the inhibitory brain neurotransmitter γ-aminobutyric acid. Primary groups using GHB include party and nightclub attendees. Like flunitrazepam, GHB is also characterized as a date rape drug.\(^{14}\) Manifestations of acute GHB toxicity include coma, seizures, respiratory depression, and vomiting. Other documented effects of GHB include amnesia and hypotonia, abnormal sequence of rapid eye movement (REM) and non-REM sleep, and anesthesia. Doses greater than 50 mg/kg can decrease cardiac output and produce severe respiratory depression, seizure-like activity, and coma; coma and respiratory depression can be potentiated by concomitant use of alcohol. Treatment is restricted to nonspecific supportive care. Figure 74-1 shows a protocol recommended for treating suspected GHB overdose.

Until fairly recently, the majority of GHB sold on the streets was manufactured using inexpensive kits obtained over the Internet. The decreased Internet availability of kits to make GHB has been accompanied by an increased availability of chemical precursors to GHB as well as GHB analogs. Available in gyms and health food stores, these substances include γ-butyrolactone (GBL) and 1,4-butanediol.\(^{17}\) GBL is converted in the body to GHB. Labels of marketed products can use unfamiliar synonyms to disguise the actual content. GBL is also known by the names 2(3H)-furanone dihydro, butyrolactone, 4-butyrolactone, dihydro-2(3H)-furanone, 4-butanolide, 2(3H)-furanone, dihydro, tetrahydro-2-furanone, and butyrolactone-γ.

GHB is being used and is being studied for a number of legitimate medical uses, including its use as an anesthetic, treatment of narcolepsy, and treatment of drug addiction. In fact, a pharmaceutical version of GHB (called by the alternate name of sodium oxybate [Xyrem]) was approved by the U.S. Food and Drug Administration (FDA) for cataplexy attacks in patients with narcolepsy in 2002. In November 2005, the FDA approved sodium oxybate for the treatment of excessive daytime sleepiness in patients with narcolepsy. Deaths from the pharmaceutical dosage forms have been reported.\(^{18}\)

CARISOPRODOL

Carisoprodol is a prescription drug marketed since 1959 and used in primary care settings for the treatment of musculoskeletal conditions associated with muscle spasms and back pain. Its effectiveness for this use has been questioned.\(^{19}\) It is marketed in the United States as Soma and in the U.K. as Carisoma as well as many generic versions. It is both structurally and pharmacologically related to meprobamate, a schedule IV substance. In fact, a substantial percentage of the drug is metabolized to meprobamate,\(^{19}\) a drug with substantial barbiturate-like properties.

In legitimate medical practice carisoprodol is used as an adjunct to rest, physical therapy and other measures for relief of acute, painful musculoskeletal conditions. The standard dosage for adults is 350 mg 3 times daily and at bedtime. Approximately 10.58 million prescriptions for carisoprodol were dispensed in 2008. Skeletal muscle relaxant effects of carisoprodol may be related to its sedative properties.\(^{19,20}\) Adverse effects are mostly related to

![Figure 74-1](image-url)
the CNS: drowsiness, dizziness, vertigo, ataxia, tremor, agitation, irritability, headache, depressive reactions, syncope, and insomnia. Carisoprodol may also adversely affect cardiovascular (tachycardia, postural hypotension, and facial flushing), gastrointestinal (nausea, vomiting, hiccup, and epigastric distress), and hematologic systems. It may cause idiosyncratic symptoms including extreme weakness, transient quadriplegia, ataxia, difficulty in speech, temporary loss of vision, double vision, dilated pupils, agitation, euphoria, confusion, and disorientation. Carisoprodol overdose has resulted in stupor, coma, shock, respiratory depression, and death.20–22

Data are clear that the diversion and abuse of carisoprodol have increased in the last decade.19 According to 2007 NSDUH data, nonmedical use of carisoprodol by the U.S. population aged 12 and older was 1.1%, similar to or greater than the prevalence of abuse of other commonly abused schedule IV controlled drugs such as clonazepam (1.5%) and chloridiazepoxide (0.3%).3 With prolonged abuse at high dosage, carisoprodol can lead to tolerance, dependence, and withdrawal symptoms in humans.20

According to the Diversion Drug Trends, published by the DEA on the trends in the diversion of controlled and noncontrolled pharmaceuticals,19 carisoprodol continues to be one of the most commonly diverted drugs. Diversion and abuse of carisoprodol is prevalent throughout the country.

Iironically, carisoprodol is not controlled under the federal Controlled Substances Act of 1970. It is currently scheduled under state law in Alabama, Arizona, Arkansas, Florida, Georgia, Hawaii, Indiana, Kentucky, Louisiana, Massachusetts, Minnesota, Nevada, New Mexico, Oklahoma, Oregon, Texas, and West Virginia.

OPIATES

The National Household Survey on Drug Abuse indicated that an estimated 3,091,000 U.S. residents aged 12 and older have used heroin at least once in their lifetime. Collectively, use of opiates other than heroin is far more common. Of the 12 years of age and older population, an estimated 4.7 million people used narcotic pain relievers nonmedically and 3.1 million persons used what Substance Abuse and Mental Health Services Administration classified as “OxyContin” nonmedically at least once in their lifetime.23

PRESENTATION OF OPIOID INTOXICATION AND WITHDRAWAL

General

■ Onset of the acute phase of withdrawal ranges from a few hours after stopping heroin to 3 to 5 days after stopping methadone. The duration of withdrawal ranges from 3 to 14 days.

■ Opioid withdrawal is not fatal unless there is a concurrent medical problem of major concern.

■ The presence of delirium should raise the question of concurrent withdrawal from another drug, such as alcohol, or another cause of delirium possibly secondary to drug use.

Symptoms

■ During withdrawal, patients can experience piloerection, insomnia, muscle aches, and yawning. While intoxicated, patients can experience euphoria, dysphoria, apathy, sedation, or attention impairment.

Signs

■ Fever, lacrimation, diaphoresis, or diarrhea may be observed during withdrawal. Motor retardation, slurred speech, and miosis may be observed during intoxication.

Laboratory Tests

■ Treatment is based more on clinical presentation because plasma opioid levels may not be clinically useful.

Other Diagnostic Tests

■ Arterial blood gases, pulse oximetry, and pulmonary function tests are useful to assess respiratory depression.

By crushing controlled-release tablets, drug abusers can get the full 12-hour or more of narcotic effect almost immediately. Snorting or injecting the crushed tablet can lead to overdose and death. Abuse of this drug has caused a nationwide discussion on whether drugs of this nature should be more closely regulated. Various position statements and points of view on the benefits and risks have been expressed, but the limited space here precludes an exhaustive review of the issues. An excellent review of the appropriate use of opioid therapy for chronic pain has recently been published, and the interested reader is directed there for more information.24

CLINICAL CONTROVERSY

There is considerable debate about the appropriate use of prescribed opiates and how this might contribute to the overdose or abuse of these same drugs for nonmedicinal purposes. Not all decisions that physicians and other prescribers make are going to be correct. Likewise, pharmacists are going to make the wrong decision by either declining to fill a prescription that is proper and appropriate or by filling one that is bogus. In the final analysis, mistakes in judgment are going to be made in both directions. Given this fact, in which direction should the health professional err? Should health practitioners give the patient the benefit of the doubt, writing or filling the prescription, even if their decision ultimately turns out to be wrong? Or should the mandate be in the other direction: refuse to prescribe pain medicines or refuse to fill the prescriptions, even when, in truth, the prescription is appropriate and valid? Most healthcare professional assume that complaints of pain are real and prescribe accordingly.

METHADONE

The use of methadone has increased sharply, partially in response to the increased scrutiny given oxycodone products in the past few years. Methadone prescriptions for pain management grew from about 531,000 in 1998 to about 4.1 million in 2006, a nearly eightfold increase. The FDA approved methadone for treating pain in 1947, but from the early 1970s until the late 1990s, the drug was primarily used for treating addiction. In the mid-1990s, various national pain-related organizations began to issue guidelines for treating and managing pain, including using opioids to treat both cancer and noncancer pain. At first, methadone was prescribed more for the treatment of cancer pain, but it has been increasingly prescribed for the treatment of chronic noncancer pain. Methadone’s advantages include that it costs less than other opioids used to treat pain, and it comes in multiple forms.25

Methadone has pharmacologic properties unique among opioids, and as a result, a lack of knowledge about methadone among practitioners and patients has been identified as a factor contributing to the increased number of deaths observed in recent years. DEA data suggest that the abuse of methadone diverted from its intended purpose has also contributed to the rise in overdose deaths, as the
number of methadone drug items seized by law enforcement and analyzed in forensic laboratories increased 262%, from 2,865 in 2001 to 10,361 in 2007.21

To improve safety, in 2006, the FDA issued a Public Health Advisory22 that included new labeling information regarding the use of methadone for pain and modified dosage instructions for those beginning pain management treatment with methadone. Methadone’s elimination half-life (8–59 hours) is longer than its duration of analgesic action (4–8 hours). Healthcare professionals were reminded that methadone’s peak respiratory depressant effects typically occur later, and persist longer than its peak analgesic effects. The FDA advised that during treatment initiation, methadone’s full analgesic effect is usually not attained until 3 to 5 days of dosing.

Cross-tolerance between methadone and other opioids is incomplete. This incomplete cross-tolerance makes the conversion of patients on other opioids to methadone complex and does not eliminate the possibility of methadone overdose, even in patients tolerant to other opioids. Deaths have been reported during conversion from chronic, high-dose treatment with other opioid agonists to methadone. It is critical to understand the pharmacokinetics of methadone when converting patients from other opioids to methadone. Particular vigilance is necessary during treatment initiation, during conversion from one opioid to another, and during dose adjustments. Also, there are pharmacokinetic and pharmacodynamic drug interactions between methadone and many other drugs. Thus drugs administered concomitantly with methadone should be evaluated for interaction potential.26

DEXTROMETHORPHAN

Dextromethorphan abuse is one of the most common (and most dangerous) examples of OTC drug abuse.27 Intoxication from consuming large doses of cough syrup is known on the street as “robodosing” or “robotripping.” Handsful of cough and cold remedies are sometimes called “skittles” because they look similar to the popular fruit candy. Dextromethorphan creates a depressant and mild hallucinogenic effect when taken in large doses. Since the drug is available over the counter, it is easily procured by adolescents. Those who use the cough syrup to get high are sometimes called “syrup heads.”27

Excessive doses are needed to induce effects that include hyperexcitability, lethargy, ataxia, slurred speech, diaphoresis, hypertension, nystagmus, and mydriasis. When taken at much higher doses, it acts as a dissociative anesthetic, similar to phencyclidine (PCP, “angel dust”) and ketamine (“Special K”). These are the effects sought by those who use the drug to get high. At these high doses, dextromethorphan also is a CNS depressant.27,28

The recommended treatment for acute overdoses of dextromethorphan is naloxone. Although reports of its efficacy are mixed, it may be helpful in reversing the CNS depressant and neurologic effects.24

Dextromethorphan powder is available through the Internet and by home laboratory extraction from pharmaceutical products. Five deaths in the United States have been attributed to dextromethorphan powder sold over the Internet.27

CNS STIMULANTS

COCAINE

Cocaine is absorbed rapidly from virtually all sites of application. For many years, cocaine has been administered as the hydrochloride salt form, usually by inhalation, but also by injection. In the last 18 to 20 years, as the purity of cocaine hydrochloride obtained on the street declined, many users converted the cocaine hydrochloride to cocaine base, also known as “crack” or “rock.” Smoking the drug leads to almost instant absorption and intense euphoria. Peak plasma concentrations of more than 900 ng/mL (3.0 μmol/L) have been achieved following inhalation of cocaine base vapors, compared with concentrations of only 150 to 200 ng/mL (0.49 to 0.66 μmol/L) achieved after inhalation of similar amounts of pure cocaine hydrochloride powder.29

The high from snorting can last 15 to 30 minutes, whereas that from smoking can last 5 to 10 minutes. Increased use can reduce the period of stimulation. An appreciable tolerance to the high can be developed, and many addicts report that they seek but fail to achieve as much pleasure as they did from their first exposure. Scientific evidence suggests that the powerful neuropsychologic reinforcing property of cocaine is responsible for an individual’s continued use despite harmful physical and social consequences.
Recent research has helped clarify certain patterns of cocaine use, such as combining cocaine and alcohol. Such drug use would seem counterintuitive because cocaine is a CNS stimulant, and alcohol a CNS depressant. In the presence of alcohol, cocaine is metabolized to cocaethylene, a longer-acting but potent psychoactive compound compared to the parent drug. The risk of death from cocaethylene is greater than from cocaine. The cocaine-alcohol combination is one of the most commonly identified among individuals who come to hospital EDs with acute substance abuse problems. Cocaine is metabolized and eliminated rapidly. The elimination half-life of cocaine is approximately 1 hour, and the duration of effect is very short. The short duration of effect provides a powerful incentive for repeated use of the drug. Many users experience intense drug use cycling, sometimes lasting days, characterized by rapidly repeating doses of cocaine until their supply is exhausted. Laboratory monkeys, given a choice between food and cocaine around the clock for 8 days, consistently choose cocaine.

Complications of cocaine use frequently involve cardiovascular events. Cocaine is a psychotomimetic drug, sometimes even at nontoxic doses. A kindling phenomenon has been described with cocaine in which neuronal function becomes altered with each dose of the drug. The psychosis is qualitatively very similar to a paranoid schizophrenic psychosis. Although there is some controversy as to whether cocaine is associated with physical withdrawal on abrupt discontinuation, most clinicians feel that there is a characteristic syndrome of withdrawal effects, although they are not life-threatening.

**AMPHETAMINE, METHAMPHETAMINE, AND OTHER STIMULANTS**

According to the United Nations Office of Drugs and Crime, worldwide between 16 and 51 million people aged 15 to 64 used amphetamines-group substances at least once in 2007. In the United States, people who reported that they had used methamphetamine in the previous month also dropped dramatically, from 529,000 people in 2007 to 314,000 in 2008.

Street methamphetamine is referred to by many names, such as “speed,” “meth,” and “crank.” Methamphetamine hydrochloride, clear chunky crystals resembling ice, can be inhaled by smoking. It is referred to as “ice,” “crystal,” and “glass” on the street.

The physiologic and psychologic effects of amphetamines and other stimulants are qualitatively similar to those of cocaine—they diminish fatigue, increase alertness, and suppress appetite. Pharmacologically, amphetamines increase the activity of catecholamine neurotransmitters (e.g., norepinephrine and dopamine) by increasing release and by inhibiting the degradative enzyme monoamine oxidase. The longer duration of effect of methamphetamine has led to a shift away from cocaine and toward this longer-acting drug.

An analysis produced by the Rand Corporation suggests that the economic cost of meth use in the United States reached $23.4 billion in 2005. Because of the difficulty in pinpointing the role of methamphetamine in crime, medical care and other factors, the RAND researchers gave a range of estimates, saying the overall toll may be as low as $16.2 billion or as high as $48.3 billion.

These estimates include the burden of addiction, premature death, drug treatment, and many other costs associated with methamphetamine use. The RAND analysis found that nearly two thirds of the economic costs caused by methamphetamine use resulted from the burden of addiction and an estimated 900 premature deaths among users in 2005. For a sobering look at the methamphetamine epidemic in the United States the interested reader should view the full report.

Methamphetamine is used orally, intranasally, rectally, by intravenous injection, and by smoking. Immediately after inhalation or intravenous injection, the methamphetamine user experiences an intense sensation, called a “rush” or “flash,” that lasts only a few minutes and is described as extremely pleasurable.

**PRESENTATION OF AMPHETAMINE INTOXICATION AND WITHDRAWAL**

### General
- Amphetamine intoxication is an acute condition that may result in death. Pharmacotherapy may be indicated for symptomatic control of seizures.
- Patients may experience withdrawal symptoms for several days, but are usually not in acute distress. Treatment is supportive in nature. Pharmacotherapy is not effective to treat the symptoms of amphetamine withdrawal.

### Symptoms
- Depression, altered mental status, drug craving, dysomnias, and fatigue are all symptoms of withdrawal.
- Amphetamine intoxication may present as increased wakefulness, increased physical activity, decreased appetite, increased respiration, hyperthermia, and euphoria. Other CNS effects include irritability, insomnia, confusion, tremors, convulsions, anxiety, paranoia, chest pain, and aggressiveness. Hyperthermia and convulsions can result in death.

### Signs
- Patients with amphetamine intoxication may present with tachycardia, hypertension, or stroke.

### Laboratory Tests
- A qualitative drug of abuse urine screening is used for diagnostic purposes. Confirmatory blood tests with gas chromatography and mass spectrophotometry may be used for verification.

Because methamphetamine elevates mood, people who experiment with it tend to use it with increasing frequency and in increasing doses, although this was not their original intent. The timing and intensity of the “rush” that accompanies the use of methamphetamine, which is a result of the release of high levels of dopamine in the brain, depends in part on the method of administration. Specifically, the effect is almost instantaneous when smoked or injected, whereas it takes approximately 5 minutes after snorting or 20 minutes after oral ingestion. Prolonged use of methamphetamine can result in a tolerance for the drug and increased use at higher dosage levels, creating dependence. Such continual use of the drug with little or no sleep may lead to an extremely irritable and paranoid state. Discontinuing use of methamphetamine often results in a state of depression, as well as fatigue, anergia, and some types of cognitive impairment that can last from 2 days to several months.

Both short- and long-term health effects have also been documented. Negative consequences of methamphetamine abuse range from anxiety and insomnia to convulsions, paranoia, and brain damage. Methamphetamine-induced caries, or “meth mouth” is a characteristic pattern of dental decay commonly observed in patients that smoke methamphetamine.

In addition to the many direct effects on methamphetamine users are the indirect impacts on individuals and society. Flammable ingredients that include acetone, red phosphorous, ethyl alcohol, and lithium metal are used in methamphetamine cookers, often with disastrous results. Fires and explosions often ensue, resulting in severe burns and uncovering laboratories to local law enforcement. According to the United Nations Office of Drugs and Crime, worldwide between 16 and 51 million people aged 15 to 64 used amphetamines-group substances at least once in 2007. In the United States, people who reported that they had used methamphetamine in the previous month also dropped dramatically, from 529,000 people in 2007 to 314,000 in 2008.
effective treatment for methamphetamine dependence can be one
of the most important strategies in reducing the spread of HIV and other associated communicable diseases. Treatment for methamphetamine dependence is very difficult, and has a low success rate.\(^5\)

The expanding global market is fed by an increase in clandestine manufacture of methamphetamine. Not only are there more laboratories in more countries, but their size and sophistication are also increasing. The number of clandestine methamphetamine laboratories seized nationwide by the DEA increased from 263 in 1994 to 1,815 in 2000, a 590% increase.\(^4\) In 2008, state and local police agencies seized almost 6,783 clandestine laboratories in the United States. So-called “kitchen” laboratories are still discovered, but today clandestine laboratories with 100-kg capacities per week are also found. Initially the clandestine manufacture of methamphetamine was based primarily in the West and Southwest.\(^4\) Today methamphetamine can be found in cities across the United States, although local law enforcement pressures have caused a decrease in “superlaboratories” capable of producing at least 10 pounds per production cycle.\(^5\) Unfortunately, increased methamphetamine production by Mexican drug cartels has offset the decreased domestic production.

Methamphetamine is manufactured using the ephedrine or pseudoephedrine reduction method. In this process, ephedrine or pseudoephedrine is extracted from OTC cold and allergy tablets. Pharmacists should be wary of persons wishing to purchase large quantities of products containing nonprescription sympathomimetic products. As a precaution, federal legislation now mandates that pseudoephedrine-containing products be kept behind a counter, and suitable identification must be shown before they can be purchased.

ECSTASY AND OTHER METHAMPHETAMINE ANALOGS

Several dozen analogs of amphetamine and methamphetamine are mildly hallucinogenic. Two methamphetamine analogs of most concern are 3,4-methylenedioxymethamphetamine and especially 3,4-methylenedioxymethylamphetamine (MDMA or Ecstasy). Use of these compounds was particularly prevalent in the early 2000s. However, annual prevalence rates for ecstasy dropped considerably between 2000 and 2008, from 3.1% to 1.7% for 8th graders, from 5.4% to 2.9% for 10th graders, from 8.2% to 4.3% for 12th graders, from 9.1% to 3.7% among college students, and from 7.2% to 3.3% among young adults.\(^6\)

The effects of MDMA usually last approximately 4 to 6 hours. Users of the drug say that it produces profoundly positive feelings, empathy for others, elimination of anxiety, and extreme relaxation. MDMA is also said to suppress the need to eat, drink, or sleep, enabling users to endure 2- to 3-day parties. Consequently, MDMA use sometimes results in severe dehydration or exhaustion. MDMA generally reduces inhibitions and creates a sense of euphoria, but it also can evoke anxiety and paranoia. Heavier doses generate depression, irrationality, and psychosis. Users claim they experience feelings of closeness with others and a desire to touch them.

MDMA use can result in a variety of acute psychiatric disturbances, including panic, anxiety, depression, and paranoid thinking.\(^7\) Physical symptoms include muscle tension, nausea, blurred vision, faintness, chills, and sweating. MDMA also increases the heart rate and blood pressure. Other effects include hyperthermia, dehydration, vomiting, tremors, loss of control over body movements, insomnia, convulsions, rapid eye movements, and teeth and jaw clenching.

MDMA is perceived to be a harmless drug by many of its users, based in part on the fact that the risk of death is low compared with other drugs such as heroin and cocaine. However, mounting evidence points to neurotoxic effects of MDMA, involving a complex and incompletely understood mechanism. MDMA has been clearly shown to destroy serotonin-producing neurons in animals.\(^8\) Doses of MDMA that produce neurotoxicity are only 2 or 3 times the minimum dose needed to produce a psychotropic response.

Researchers have found that heavy MDMA users have memory problems that persist for at least 2 weeks after they have stopped using the drug.\(^9\) McCann and colleagues\(^10\) conducted several studies to determine the effects of MDMA use on cognitive performance. MDMA users and controls were found to perform similarly on several cognitive tasks. However, MDMA subjects had significant performance deficits on a sustained-attention task requiring arithmetic calculations, a task requiring complex attention and incidental learning, a task requiring short-term memory, and a task of semantic recognition and verbal reasoning. The authors believe that their data provide further evidence that MDMA is neurotoxic to brain serotonin neurons in humans, and the behavioral data suggest that brain serotonin injury is associated with subtle but significant cognitive deficits.

Manufacturers of illicit drugs sometimes substitute other, potentially more dangerous substances for the one the buyer is expecting. Other suppliers produce products adulterated with chemical byproducts of the incomplete processing of active ingredients. One such chemical, \textit{para}-methoxymethamphetamine, is a drastically more potent hyperthermic agent than MDMA. Deaths from this chemical have been reported.\(^11\)

HALLUCINOGENS

The drugs commonly classified as hallucinogens are lysergic acid diethylamide (LSD), psilocybin, dimethyltryptamine (DMT), mescaline, and other related compounds. LSD is one of the most potent mood-changing chemicals. It is manufactured from lysergic acid, which is found in ergot, a fungus that grows on rye and other grains.

Pharmacologically, LSD and related drugs stimulate both presynaptic (5-hydroxytryptamine [HT] \(1A\), and 5-HT \(1B\)) and postsynaptic (5-HT\(2\)) serotonin receptors in the brain, which functionally can cause either agonist or antagonist effects on serotonin activity.\(^12\) Precisely how the hallucinogens exert their effects remains unclear. LSD is an extraordinarily potent compound, producing observable CNS effects at doses as low as 25 mcg.

LSD is sold on the street in tablets, capsules, and occasionally in liquid form. It is odorless, colorless, and tasteless and usually is taken by mouth. Often LSD is added to absorbent paper, such as blotter paper, and divided into small decorated squares, with each square representing one dose.

The effects of LSD are unpredictable. They depend on the amount taken; the user’s personality, mood, and expectations; and the surroundings in which the drug is used. Usually the user feels the first effects of the drug 30 to 90 minutes after taking it. The physical effects include dilated pupils, higher body temperature, increased heart rate and blood pressure, sweating, loss of appetite, sleeplessness, dry mouth, and tremors.

Sensations and feelings change much more dramatically than the physical signs. The user can feel several different emotions at once or swing rapidly from one emotion to another. If taken in a large enough dose, the drug produces delusions and visual hallucinations. The user’s sense of time and self changes. Sensations can seem to “cross over,” giving the user the feeling of hearing colors and seeing sounds.
Many LSD users experience flashbacks, or recurrence of certain aspects of a person’s experience, without the user having taken the drug again. A flashback occurs suddenly, often without warning, and can occur within a few days or more than a year after LSD use. Flashbacks usually occur in people who use hallucinogens chronically or have an underlying personality problem; however, otherwise healthy people who use LSD occasionally also can have flashbacks.

Most users of LSD voluntarily decrease or stop its use over time. LSD is not considered an addictive drug because it does not produce compulsive drug-seeking behavior. However, as with many of the addictive drugs, LSD use produces tolerance, so some users who take the drug repeatedly must take progressively higher doses to achieve the state of intoxication that they had achieved previously.

Psychologic symptoms of intoxication include a subjective intensification of perceptions, depersonalization, illusions, hallucinations, and synesthesias, the overflow of one sensory modality to another. LSD is the most potent and longest-acting hallucinogen; it is hundreds of times more potent than both psilocybin and mescalin. DMT is inactive when ingested orally but can be smoked, inhaled, or injected. There is cross-tolerance among LSD, psilocybin, and mescaline. There is no observable physical withdrawal syndrome after abrupt discontinuation of hallucinogenic drugs. Complications from hallucinogen use are primarily psychologic. Users sometimes experience prolonged episodes of panic—the so-called “bad trip.” The flashbacks noted above are common, occurring in approximately 15% of users and occurring episodically up to several years after the last exposure to the drug. Flashbacks can occur spontaneously but are also triggered by other drugs, including marijuana, and by anxiety-provoking stimuli. Contrary to a widely held notion in the 1960s and early 1970s, there is no reliable evidence that hallucinogen use causes chromosome damage or genetic defects.

**MARIJUANA**

Marijuana, referred to as “reefer,” “pot,” “grass,” or “weed,” was the most commonly used illicit drug in 2008. Among persons aged 12 or older, the rate of past month marijuana use in 2008 (6.1%) was similar to the rate in 2007 (5.8%). Of those, 54.5% used only marijuana, and 19.6% used marijuana and another illicit drug. In 2008, marijuana was used by 75.7% of current illicit drug users and was the only drug used by 57.3% of them. The rate of marijuana use for youth, while well off peak levels of the late 1990s, has edged up in the past year. According to the most recent Monitoring for the Future study, among 12th-graders 20.6% said they used it within the past month, compared with 19.4% in 2008 and 18.3% in 2006. Among 10th-graders, pot use in the past month rose to 15.9% this year from 13.8% in 2008. In the past year, the share of 8th-graders who smoked marijuana was 11.8%, compared with 10.9% in 2008. Tenth-graders’ use was 26.7% this year and 23.9% in 2008. The percentage of 12th-graders was 32.8% compared with 32.4% in 2008.

Most users smoke marijuana in hand-rolled cigarettes (joints), while some use pipes or water pipes (bongs). Marijuana cigars called blunts have also become popular. To make blunts, users slice open cigars and replace the tobacco with marijuana. Marijuana also is used to brew tea and is sometimes mixed into foods.

Marijuana’s effects begin immediately after the drug enters the brain and last from 1 to 3 hours. If marijuana is consumed in food or drink, the short-term effects begin more slowly, usually in 30 minutes to 1 hour, and last longer, for as long as 4 hours. Smoking marijuana delivers several times more of its major active ingredient, delta-9-tetrahydrocannabinol (THC) into the blood than does eating or drinking the drug.
much debate. Undoubtedly, opinions on its risks are polarized along the lines of proponents’ views on what its legal status should be. This polarization of opinion has prevented the development of any consensus on what health information the medical profession should give to patients who are users or potential users of marijuana. There is conflicting evidence about many of the effects of marijuana use. Readers are referred to two excellent articles that attempt to summarize in a dispassionate way the evidence on the most probable adverse health and psychologic consequences of acute and chronic use of marijuana. 32,33

**CLINICAL CONTROVERSY**

The mere mention of the words “medical marijuana” is bound to evoke strong emotions among laypersons and healthcare professionals alike. While the federal government continues to enforce laws that make possession and use of marijuana illegal, regardless of the intended purpose, at last count 13 of the U.S. states have legalized medical marijuana. While the safety and efficacy of marijuana to treat certain identifiable medical conditions has been confirmed, many other uses are supported by anecdote or limited clinical experience. However, the debate involves much more than whether cannabis works or not to treat illness. Instead, there are political, social, economic, and religious considerations that cloud the controversy over whether marijuana should be legalized for medical purposes. This debate is bound to continue for years to come.

**INHALANTS**

Inhalants are a diverse group of substances that include volatile solvents, gases, and nitrates that are sniffed, snorted, huffed, or bagged to produce intoxicating effects similar to those of alcohol. These substances are found in common household products such as glues, lighter fluid, cleaning fluids, paint products, nail polish remover, gasoline, rubber glue, waxes, and varnishes. Chemicals found in these products include toluene, benzene, methanol, methylene chloride, acetone, methyl ethyl ketone, methyl butyl ketone, trichloroethylene, and trichloroethane. The gas used as a propellant in canned whipped cream and in small metallic containers called “whippets” (used to make whipped cream) is nitrous oxide or “laughing gas.” Tiny cloth-covered ampules called “poppers” or “snappers” by abusers contain amyl nitrite, a medication used to dilate blood vessels. Butyl nitrite, sold as tape head cleaner and referred to as “rush,” “locker room,” or “climax,” is often sniffed or huffed to get high.

Inhalants can be sniffed directly from an open container or huffed from a rag soaked in the substance and held to the face. Alternatively, the open container or soaked rag can be placed in a bag where the vapors can concentrate before being inhaled. Although inhalant abusers might prefer one particular substance because of taste or odor, a variety of substances can be used because of similar effects, availability, and cost. Once inhaled, the extensive capillary surface area of the lungs allows rapid absorption of the substance, and blood levels peak rapidly. Entry into the brain is fast, and the intoxicating effects are intense but short lived. Intoxication is often accompanied by headache and nausea, and users can experience hallucinations and delusions. The most serious physical risk of acute use is sudden death, usually from cardiac arrhythmias. Some users die from suffocation by plastic bags that contain the solvent. With chronic use, the drugs are toxic to virtually all organ systems. Psychologic impairment; impaired pulmonary, renal, and hepatic function; neuropathies; encephalopathy; and brain damage have all been observed.

Inhalants depress the CNS, producing decreased respiration and blood pressure. Users report distortion in perceptions of time and space. Many users experience headaches, nausea, slurred speech, and loss of motor coordination. A rash around the nose and mouth can be seen, and the abuser can start wheezing. An odor of paint or organic solvents on clothes, skin, and breath is sometimes a sign of inhalant abuse. Other indicators of inhalant abuse include slurred speech or staggering gait; red, glassy, watery eyes; and excitability or unpredictable behavior.

**TREATMENT**

**Substance-Related Disorders**

**ACUTE DRUG INTOXICATIONS**

Treatment of drug intoxication, summarized in Table 74-2, is primarily supportive. Vital functions are maintained while waiting for the drug to be eliminated. Whenever possible, drug therapy should be avoided because psychotropic drug therapy has the potential for worsening a toxic reaction to another psychoactive substance, and blood levels peak rapidly. Entry into the brain is fast, and the intoxicating effects are intense but short lived. Intoxication is often accompanied by headache and nausea, and users can experience hallucinations and delusions. The most serious physical risk of acute use is sudden death, usually from cardiac arrhythmias. Some users die from suffocation by plastic bags that contain the solvent. With chronic use, the drugs are toxic to virtually all organ systems. Psychologic impairment; impaired pulmonary, renal, and hepatic function; neuropathies; encephalopathy; and brain damage have all been observed.

*Strength of recommendations, evidence to support recommendation, A, good; B, moderate; C, poor.

*Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from O’Brien, 32 Fudala et al, 33 Smith and Seymour, 33 and Knapp et al. 34
agent; however, when patients are agitated, combative, assaultive, hallucinating, or delusional, drug therapy may be required. Toxicology screens are useful in the evaluation and treatment process, but knowledge of the metabolism of the suspected drug and its excretion patterns is important for proper interpretation of test results. When toxicology screens are desired, blood or urine should be collected immediately upon the patient’s arrival.

For alcohol and barbiturate intoxication, supportive treatment is the rule. For benzodiazepine intoxication, the benzodiazepine antagonist flumazenil can be used to reverse toxic effects. In the case of opiate intoxication, if the patient is unconscious and respiration is depressed, the opiate antagonist naloxone can be used to revive the patient. The usual dosage for naloxone in acute opiate toxicity is 0.4 to 2 mg intravenously, given approximately every 3 minutes as necessary. Although naloxone is effective in reversing opiate overdose, it also can precipitate physical withdrawal in physically dependent patients.

Intoxication with stimulants, including cocaine, is treated pharmacologically only if the patient is overtly psychotic and agitated. Injectable benzodiazepines, usually lorazepam 2 to 4 mg intramuscularly every 30 minutes to 6 hours as necessary, can be used for agitation. As a backup to lorazepam, antipsychotic drugs can be used on a short-term basis, primarily in patients with psychotic symptoms, and usually at relatively low doses, such as haloperidol 2 to 5 mg intramuscularly every 30 minutes to 6 hours as necessary, followed by 5 to 15 mg orally per day in single or divided doses if the patient is still psychotic after initial treatment.

A recent evidence-based guideline gives precise recommendations for treating the cardiovascular complications of cocaine abuse and provides insight into the epidemiology, pathophysiology, treatment, and prognosis of the cardiac effects of cocaine. Seizures generally are treated supportively. Intravenous lorazepam or diazepam can be used if seizures progress to status epilepticus.

Hallucinogen intoxication is treated in a manner similar to stimulant intoxication. Drug therapy often can be avoided because patients can respond to careful reassurance, or so-called talk-down therapy. When necessary, short-term antianxiety and/or antipsychotic drug therapy can be used, as described previously.

## WITHDRAWAL

Treatment of drug withdrawal is the primary indication for drug therapy in substance-related disorders. Goals of drug therapy include prevention of progression of withdrawal to life-threatening severity, and enabling the patient to be sufficiently comfortable and functional to participate in a behavioral treatment program and supportive drug therapy. The clinician should remember that withdrawal is usually part of a substance dependence disorder. In drug therapy for withdrawal, it is important to avoid reinforcing the patient’s drug-seeking and drug-use behavior to the extent possible. Patients must be educated to deal with the stress of withdrawal without seeking drugs. A recent review on the management of drug and alcohol withdrawal has been published. Treatment of drug withdrawal is summarized in Table 74–3.

## CNS DEPRESSANT WITHDRAWAL

### Benzodiazepines

Treatment of benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal. The major difference in management is the length of treatment. The onset of withdrawal symptoms in patients physically dependent on the long-acting benzodiazepines can be delayed up to 7 days after discontinuation of the drug. A common approach in detoxification of such patients is to initiate treatment at usual dosages (chlordiazepoxide orally 50 mg to 3 times a day; lorazepam orally 2 mg 3 times a day) and to maintain the initial dosage for 5 days, with gradual tapering over an additional 5 days.

Detoxification in patients physically dependent on shorter-acting benzodiazepines is similar to treatment of alcohol withdrawal. Among the benzodiazepines, alprazolam has been suggested to be more difficult to taper and discontinue than the other benzodiazepines. A longer, more gradual taper of the benzodiazepine used for detoxification can be needed. With all benzodiazepines, protracted minor abstinence symptoms—such as anxiety, insomnia, irritability, sensitivity to light and sound, and muscle spasms—can remain for several weeks in patients with a history of long exposure, even after the acute phase of benzodiazepine withdrawal is complete.

### Barbiturates and Other Sedative-Hypnotic Drugs

Although once used extensively, barbiturates and other nonbenzodiazepine sedating medications have been largely replaced by safer and more effective medications. Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways. Withdrawal from barbiturates should be handled similarly to interventions for...
the abuse of alcohol and benzodiazepines. Specific recommendations have been suggested for zolpidem withdrawal.

Opiates

Opiate withdrawal syndrome is similar to a severe case of influenza. It is not life-threatening unless there is a concurrent life-threatening medical condition. Although most patients complain of symptoms of withdrawal such as cramping or insomnia, these symptoms are tolerable, and initiation of drug therapy can be avoided in many cases. Observable signs of withdrawal should be noted before initiation of drug therapy. Characteristic signs and symptoms of opiate withdrawal include pupillary dilatation, lacrimation, rhinorrhea, piloerection ("gooseflesh"), yawning, sneezing, anorexia, nausea, vomiting, and diarrhea. Seizures do not occur. Onset and duration of withdrawal symptoms and the time of peak occurrence depends on the half-life of the drug involved. Typically heroin withdrawal reaches a peak within 36 to 72 hours of discontinuation and can last for 7 to 10 days. For methadone, symptoms peak at 72 hours but can last for 2 weeks or more.

In the past, drug therapy for opioid withdrawal had typically been methadone, a synthetic opiate. Methadone is administered in decreasing doses over a period not exceeding 30 days (short-term detoxification) or 180 days (long-term detoxification). In 2009, a systematic review including 1907 people from twenty trials was reported. The purpose of this review was to evaluate the effectiveness of tapered methadone compared with other detoxification treatments and placebo in managing opioid withdrawal on completion of detoxification and relapse rate. Comparing methadone versus any other pharmacological treatment (e.g., adrenergic agonists [11 studies], other opioid agonists [four studies], chloridiazepoxide [one study]) the authors found no clinical difference between the two treatments in terms of completion of treatment, relative risk (RR) 1.08 (95% CI, 0.95–1.24) and results at follow-up RR 1.17 (95% CI, 0.72–1.92). The studies included in this review confirm that slow tapering with temporary substitution of long acting opioids, can reduce withdrawal severity. Nevertheless the majority of patients relapsed to heroin use.

Usually, opioid dependency is treated initially with detoxification. In the past, opioid-dependent patients relied on methadone or levo-alpha-acetylmethadol, but federal restrictions limited distribution of these drugs to a small number of methadone clinics. There were limited provisions for take-at-home dosing of methadone because of concern about the diversion of these drugs to illicit use.

### USE OF BUPRENORPHINE IN OPIATE WITHDRAWAL AND MAINTENANCE

In 2002, buprenorphine was approved for opioid withdrawal. Prior to the passage of the federal Drug Addiction Treatment Act (DATA) of 2000, office-based management of opioid dependence was illegal because existing federal laws prohibited physicians from prescribing narcotics for the sole purpose of maintaining a patient in a narcotic-addicted state.

The first of two formulations approved, Subutex, contains only buprenorphine and is intended for use at the beginning of treatment. The other, Suboxone, contains both buprenorphine and the opiate antagonist naloxone, and is intended to be used in maintenance treatment of opiate addiction. When buprenorphine with naloxone is administered sublingually, the naloxone component produces no clinically significant effect; however, after parenteral administration, naloxone-induced opioid antagonism occurs resulting in symptoms of withdrawal.

To qualify, physicians must be board certified in addiction medicine/psychiatry or hold other special credentials, and physicians are required to obtain 8 hours of authorized training before they can prescribe medications for office-based treatment of opioid dependence.

DATA 2000, as amended in December 2006, specifies that an individual physician may have a maximum of 30 patients on opiod therapy at any one time for the first year. One year after the date on which a physician submitted the initial notification, the physician may submit a second notification of the need and intent to treat up to 100 patients.

The goal of using buprenorphine for medically supervised withdrawal from opioids is to provide a transition from the state of physical dependence on opioids to an opioid-free state, while minimizing withdrawal symptoms (and avoiding side effects of buprenorphine).

Medically supervised withdrawal with buprenorphine consists of an induction phase and a dose-reduction phase. Best practice guidelines collectively called Treatment Improvement Protocols (TIPs) are periodically issued for treatment of substance use disorders. TIP 40 (the guideline for the Use of Buprenorphine in the Treatment of Opioid Addiction) provides consensus- and evidence-based guidance on the use of buprenorphine.

The statement recommends that patients dependent on short-acting opioids (e.g., hydromorphone, oxycodone, heroin) be inducted directly onto buprenorphine/naloxone tablets. The use of buprenorphine (either as buprenorphine monotherapy or buprenorphine/naloxone combination treatment) to taper off long-acting opioids should be considered only for those patients who have evidence of sustained medical and psychosocial stability, and should be undertaken in conjunction and in coordination with patients’ overall opioid treatment programs. Induction protocols are shown in Figure 74–2.

Treatment treatment with buprenorphine for opioid addiction consists of three phases: (1) induction, (2) stabilization, and (3) maintenance.

Induction is the first stage of buprenorphine treatment and involves helping patients begin the process of switching from the opioid of abuse to buprenorphine. The goal of the induction phase is to find the minimum dose of buprenorphine at which the patient discontinues or markedly diminishes use of other opioids and experiences no withdrawal symptoms, minimal or no side effects, and no craving for the drug of abuse. The consensus panel recommends that the buprenorphine/naloxone combination be used for induction treatment (and for stabilization and maintenance) for most patients. The consensus panel further recommends that initial induction doses be administered as observed treatment; further doses may be thereafter provided via prescription. To minimize the chances of precipitating withdrawal, patients who are transferring from long-acting opioids (e.g., methadone, sustained-release morphine, sustained-release oxycodone) to buprenorphine should be inducted using buprenorphine monotherapy, but switched to buprenorphine/naloxone soon thereafter.

The stabilization phase begins when a patient is experiencing no withdrawal symptoms, is experiencing minimal or no side effects, and no longer has uncontrollable cravings for opioid agonists. Dosage adjustments may be necessary during early stabilization, and frequent contact with the patient increases the likelihood of compliance. The longest period that a patient is on buprenorphine is the maintenance phase. This period may be indefinite. During the maintenance phase, attention must be focused on the psychosocial and family issues that have been identified during the course of treatment as contributing to a patient’s addiction.

Some other issues related to opioid abuse that need to be addressed during maintenance treatment include, but are not limited to, the following:

- Psychiatric comorbidity
- Somatic consequences of drug use
- Family and support issues
- Structuring of time in prosocial activities
- Employment and financial issues
- Legal consequences of drug use
- Other drug and alcohol abuse

A recent systematic review evaluating the withdrawal component of buprenorphine treatment, including twenty-two studies involving 1,736 participants, was published. The major comparisons for buprenorphine were with methadone (5 studies) and clonidine or lofexidine (12 studies). Five studies compared different rates of buprenorphine dose reduction.

The authors concluded that severity of withdrawal is similar for withdrawal managed with buprenorphine and withdrawal managed with methadone, but withdrawal symptoms may resolve more quickly with buprenorphine. It appears that completion of withdrawal treatment may be more likely with buprenorphine relative to methadone (RR 1.18; 95% CI, 0.93–1.49; \( P = 0.18 \)) but more studies are required to confirm this. 63

A rapid detoxification technique has been developed that is designed to shorten detoxification by precipitating withdrawal through the administration of opioid antagonists such as naloxone.
or naltrexone. This approach is thought to have the advantage of getting patients through detoxification rapidly, minimizing the risk of relapse, and initiating treatment more quickly with naltrexone maintenance combined with suitable psychosocial interventions. Ultrarapid detoxification represents a variant of this technique in which patients undergo opioid antagonist–precipitated withdrawal while under general anesthesia or heavy sedation. In the United States, there has been a rapid proliferation of programs offering ultrarapid detoxification, with some programs charging up to $15,000 per treatment. Rapid detoxification remains unproven and controversial.

**Withdrawal from Other Substances**

Withdrawal from other drugs, including cocaine and other stimulants, is primarily supportive. However, pharmacotherapy recently has assumed a greater role in treating cocaine withdrawal and dependence. Bromocriptine, a dopamine antagonist at low dosages and an agonist at high dosages, is usually used in the treatment of parkinsonism and hyperprolactinemia and has been used to treat cocaine withdrawal symptoms and to reduce the craving for cocaine. Use of bromocriptine is based on the hypothesis that chronic use of cocaine causes dopamine depletion; therefore higher dosages should be used (i.e., 2.5 mg 3 times daily or higher). Despite initially promising pilot studies, recent evidence does not support the efficacy of bromocriptine to reduce cocaine use or craving.

A more recent approach is the use of the cocaine vaccine that treats cocaine dependence. In the presence of the vaccine, the immune system forms antibodies that prevent cocaine from crossing the blood-brain barrier, blocking access to receptor sites in the brain. A recently published randomized, double-blind, placebo-controlled efficacy trial showed that a vaccine can prevent addicts from getting high by blocking the drug’s effect on the brain, though it apparently does not blunt cravings for the drug.

In this study, the vaccine had only limited success because it produced a suboptimal immune response in many patients. Those who reached the target antibody levels had significantly more cocaine-free urine samples than the others between the 9th and 16th weeks of the 6-month study, and 53% of them reduced their cocaine use by half, compared with only 23% in the group that was vaccinated but did not produce sufficient antibodies.

**Substance Dependence**

The treatment of drug dependence is primarily behavioral. The patient generally is taught that complete abstinence is the only realistic alternative to a life of uncontrollable drug use and despair that ultimately will end in death, and that there is no intermediate, controllable level of drinking or use of another drug. There may be an extremely few individuals who can return to controllable levels of drinking alcohol, but it is impossible to predict who these individuals are. The prospect of life without alcohol or other drugs is incomprehensible to many patients. Entry into treatment often is facilitated by some type of leverage that the drug-dependent person associates with negative consequences, such as potential loss of job, divorce, legal problems, or deteriorating physical health. Early treatment is directed at penetrating the denial of a problem that is always present. The patient must be educated as to the disease of addiction, the effects of drugs, and the permanence of the condition.

As evidenced by the approval of the two buprenorphine products, there has been a trend toward outpatient treatment for drug dependence, caused in part by cost-containment efforts. Inpatient treatment programs can cost as much as $20,000 for a 4-week stay. When withdrawal symptoms are mild to moderate and there are no other medical indications for hospitalization, outpatient treatment can be an attractive alternative to inpatient treatment. One critical criterion for outpatient treatment is the patient’s compliance with complete abstinence from the dependence-producing drug during the treatment experience.

Families must be involved in treatment. The course of the patient’s illness often has a devastating effect on other family members. Severely depleted self-esteem, denial of the family member’s addiction, feelings of responsibility for the family member’s drug use, and other behaviors that parallel the addiction process are often present.

Treatment must be a lifelong process. Aftercare, or what is now being called continued care, should include regular and frequent treatment in some form. Most drug-dependence treatment programs embrace a treatment approach based on the twelve steps to recovery. Among chemically dependent healthcare professionals, treatment that incorporates both 12-step and peer-led self-help groups can be most effective.

**Conclusions**

Substance use disorders remain one of the great public health issues of contemporary society. Dependence on drugs is a powerful emotional and political issue. Because we live in a chemically oriented society, everyone is affected in some way by drug abuse and drug dependence. Healthcare professionals must be particularly vigilant for problems associated with drug use, not only for our patients, but also for ourselves.

KEY CONCEPTS

1. Tobacco is the number 1 preventable cause of death in the United States.
2. Between 12 and 16 million Americans report current heavy alcohol use or alcohol abuse.
3. Pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients or predispose them toward alcohol dependence.
4. Alcohol is a central nervous system depressant that shares many pharmacologic properties with the nonbenzodiazepine sedative hypnotics.
5. The metabolism of alcohol is considered to follow zero-order pharmacokinetics, and this has important implications for the time course in which alcohol can exert its effects.
6. Benzodiazepines are the treatment of choice for alcohol withdrawal.
7. Disulfiram, naltrexone, and acamprosate are FDA-approved drug therapies for the treatment of alcohol dependence. The clinical utility of these agents to improve sustained abstinence remains controversial. Relapse is common.
8. More than three quarters of smokers are nicotine dependent. Tobacco dependence is a chronic condition that requires repeated interventions.
9. Use of nicotine replacement therapy along with behavioral counseling doubles cessation rates.
10. Bupropion and varenicline are efficacious alone and in combination with nicotine replacement therapy for smoking cessation.
11. Special precautions are associated with the use of varenicline for smoking cessation.
12. Caffeine’s pharmacologic actions are similar to those of other stimulant drugs. As such, abstinence from caffeine induces a distinct withdrawal syndrome that includes headache, drowsiness, and fatigue.

KEY MEDICAL TERMS

- **Caffeinism:** Caffeinism is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine.
- **Euphoria:** A mood state characterized by an exaggerated, superficial sense of well-being, characterized by extreme happiness, sometimes more than is reasonable in a particular situation.
- **Intoxication:** The development of a substance-specific syndrome after recent ingestion and presence in the body of a substance; and it is associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system.
- **Withdrawal:** The development of a substance-specific physiologic syndrome after cessation of or reduction in intake of a substance that was used regularly.

---

1. Alcohol, nicotine, and caffeine are considered by most to be socially acceptable drugs, yet they impose an enormous social and economic cost on our society. Approximately 443,000 deaths each year are attributable to tobacco use, making tobacco the number 1 preventable cause of death and disease in this country. The three leading causes of death attributable to smoking include lung cancer, chronic obstructive pulmonary disease, and ischemic heart disease.
2. In 2008, heavy drinking was reported by 6.9% of the population aged 12 or older, or 17.3 million people. More than one fifth (23.3%) of persons aged 12 or older participated in binge drinking at least once in the 30 days prior to the National Survey on Drug Use and Health in 2008. The World Health Organization estimates that there are approximately 2 billion people worldwide who consume alcoholic beverages, and 76.3 million with diagnosable alcohol-use disorders. The three leading causes of death attributable to smoking include lung cancer, chronic obstructive pulmonary disease, and ischemic heart disease.
3. In 2008, heavy drinking was reported by 6.9% of the population aged 12 or older, or 17.3 million people. More than one fifth (23.3%) of persons aged 12 or older participated in binge drinking at least once in the 30 days prior to the National Survey on Drug Use and Health in 2008. The World Health Organization estimates that there are approximately 2 billion people worldwide who consume alcoholic beverages, and 76.3 million with diagnosable alcohol-use disorders. Long-term alcohol abuse often leads to chronic disease. A causal relationship between alcohol abuse and at least 60 types of chronic disease or injury have been established (e.g., esophageal cancer, liver cancer, and cirrhosis of the liver, epileptic seizures, homicide, and motor vehicle accidents) worldwide. Nationally, according to the Drug Abuse Warning Network 2006 survey, 577,521 emergency department (ED) visits involved either alcohol in combination with another drug (all ages) or alcohol alone for patients under the age of 21. This is about one third (33%) of all drug misuse/abuse ED visits.
4. Worldwide, alcohol abuse leads to 1.8 million deaths annually. Nationally, according to the Alcohol-Attributable Deaths Report 2001-2005, 79,646 U.S. citizens with medium and high average daily alcohol consumption die each year because of alcohol-related causes, including traffic collisions and cirrhosis of the liver. Direct and indirect health and social costs of alcoholism to the nation are estimated to be $185 billion annually.
5. Caffeine is currently the most widely used psychoactive substance in the world. In the United States, 80% to 90% of adults regularly
consume behaviorally active doses of caffeine. Although research has shown that caffeine can cause a compulsive pattern of use, the prevalence of caffeine dependence and its clinical significance are difficult to determine.

ALCOHOL

EPIDEMIOLOGY OF ALCOHOL USE

Slightly more than half of Americans aged 12 or older reported being current drinkers of alcohol according to the National Survey on Drug Use and Health 2008 survey (51.6%). This translates to an estimated 129 million people, which is similar to the 2007 estimate of 126.8 million people (51.1%). More than one fifth (23.3%) of persons aged 12 or older participated in binge drinking, defined as having five or more drinks on the same occasion, at least once in the 30 days prior to the survey. This translates to about 58.1 million people. The rate in 2008 is the same as the rate in 2007 (23.3%). In 2008, heavy drinking was reported by 6.9% of the population aged 12 or older, meaning that they drank five or more drinks on the same occasion on at least five different days in the past month.

THE DISEASE MODEL OF ADDICTION AS APPLIED TO ALCOHOLISM

The disease concept of addiction, using alcoholism as a model, states that addiction is a disease, and that individuals who suffer from the disease do not choose to contract the disease any more than someone who suffers from heart disease or diabetes mellitus chooses to contract that illness. A disease is defined as "any deviation from or interruption of the normal structure or function of any part, organ, or system (or combination thereof) of the body that is manifested by a characteristic set of symptoms and signs and whose etiology, pathology, and prognosis may be known or unknown." Alcoholism, which is discussed as a prototype, meets all the definitional criteria. Diagnostic criteria for alcoholism do not specify frequency of drinking or amount of alcohol consumed. The key determinant is whether drinking is compulsive, out of control, and consequential when one drinks.

It has long been recognized that alcoholism is heritable, as 50% to 60% of first-degree relatives of alcoholics become alcohol dependent themselves. Past discussions have focused on whether this heritable risk is because of genetics, environment, or both. Recent research has identified several traits (or phenotypes), that attenuate one’s risk of alcohol dependence. Initially based on data from preclinical studies, pharmacogenomics studies have identified genotypic and functional phenotypic variants that either serve to protect patients or predispose them toward alcohol dependence. Large-scale pharmacopidemiologic studies have further elucidated the environmental risk factors that are associated with either protective effects or predisposition toward alcoholism. This is referred to as the "genome x" environment interaction effect. The known susceptibility genes, phenotypic characteristics, and environmental risk factors are summarized in Table 75-1.

PHARMACOLOGY AND PHARMACOKINETICS OF ALCOHOL

Alcohol as a Drug

Alcohol is a central nervous system (CNS) depressant that affects the CNS in a dose-dependent fashion, producing sedation that progresses to sleep, unconsciousness, coma, surgical anesthesia, and finally fatal respiratory depression and cardiovascular collapse. Alcohol affects endogenous opiates and several neurotransmitter systems in the brain, including γ-aminobutyric acid (GABA), glutamine, and dopamine. Alcohol is available in a variety of concentrations in various alcoholic beverages. There are approximately 14 g of alcohol in a 12-oz (355 mL) can of beer (approximately 5%), 4 oz (118 mL) of nonfortified wine (approximately 10%–14%), or one shot (1.5 oz [44 mL]) of 80-proof whiskey (40%). Full consumption of this amount will cause an increase in blood alcohol level of approximately 20 to 25 mg/dL (4.3 to 5.4 mmol/L) in a healthy 70-kg (154 lb) male, although this varies with the time frame over which the alcohol is consumed, the type of alcoholic beverage, whether food is consumed along with it, and many patient variables. The lethal dose of alcohol in humans is variable, but deaths generally occur when blood alcohol levels are greater than 400 to 500 mg/dL (87 to 109 mmol/L).

Data from Benjet et al, 9 Heath et al, 10 Luo et al, 11 Boothby and Doering, 12 and Krystal et al.13

CLINICAL CONTROVERSY

Moderate alcohol consumption has been suggested to improve health. The definition of moderate consumption is narrow: one drink or less per day for females, and two drinks or less per day for males. The major limitations of this research thus far are the observational study designs that cannot demonstrate cause and effect relationships between alcohol consumption and positive health benefits. Additional potential confounders in these studies include diet, exercise, disease states, other drug therapies known to promote or hinder cardiovascular health, and psychosocial factors such as stress management.

Pharmacokinetics

Absorption of alcohol begins in the stomach within 5 to 10 minutes of oral ingestion. The onset of clinical effects follows fairly rapidly. Peak serum concentrations of alcohol usually are achieved 30 to 90 minutes after finishing the last drink, although it is variable depending on the type of alcoholic beverage consumed, what and when the person last ate, and other factors.

More than 90% of alcohol in the plasma is metabolized in the liver by three enzyme systems that operate within the hepatocyte. The remainder is excreted by the lungs and in urine and sweat. Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase in the cell. In turn, acetaldehyde is metabolized to carbon dioxide and water by the enzyme aldehyde dehydrogenase.
pathway for oxidation of alcohol uses catalase, an enzyme located in the peroxisomes and microsomes. The third enzyme system, the microsomal alcohol oxidase system, has a role in the oxidation of alcohol to acetaldehyde. These last two mechanisms are of lesser importance than the alcohol dehydrogenase–aldehyde dehydrogenase system.17

The metabolism of alcohol generally is said to follow zero-order pharmacokinetics.17 This can, in fact, be an oversimplification because at very high or very low concentrations of alcohol the metabolism can follow first-order pharmacokinetics.18 On average, the blood alcohol concentration (BAC) is lowered from 15 to 22.2 mg/dL (3.3 to 4.8 mmol/L) per hour in the nontolerant individual, assuming that the individual is in the postabsorptive state (Table 75–2). Alcohol has a volume of distribution of 0.6 to 0.8 L/kg, representing the total body water.17

### CLINICAL INDICATORS OF CHRONIC ALCOHOL ABUSE

The CAGE questionnaire is a tool for detecting individuals more likely to be abusing alcohol and therefore at greater risk for alcohol withdrawal. CAGE is a mnemonic for four questions: (1) Do you ever feel the need to cut down on your alcohol use? (2) Have you ever been annoyed by others telling you that you drink too much? (3) Have you ever felt guilty about your drinking or something you did while drinking? (4) Do you ever have an “eye opener”? A positive response to two or more of these four questions suggests an increased likelihood of alcohol abuse with an average sensitivity of 0.71 (71%) and an average specificity of 0.90 (90%).19

### Acute Effects of Alcohol

At lower serum concentrations, euphoria and disinhibition may be noted. Slurred speech, altered perception of the environment, impaired judgment, ataxia, incoordination, nystagmus, and hyperreflexia may occur. As plasma levels increase combative and destructive behavior may occur. With higher levels still, somnolence and respiratory depression may ensue. The typical effects of various BACs are shown in Table 75–2, although effects vary from individual to individual.

### Alcohol Poisoning

Acute alcohol poisoning usually occurs with rapid consumption of large quantities of alcoholic beverages, because this type of drinking delivers a bolus of alcohol to the gastrointestinal (GI) tract. With sustained drinking of moderate amounts of alcohol, the user passes out before a toxic dose of alcohol can be ingested, and/or the person vomits to rid the stomach of its toxic reservoir. With rapid drinking as described, the person may fall asleep or pass out without vomiting, allowing continued alcohol absorption from the GI tract, while the patient sleeps, until fatal BACs are achieved.

### Laboratory Studies

In the emergency room, a BAC should be ordered in any patient in whom alcohol ingestion is suspected, regardless of the presenting complaint. For clinical purposes, most laboratories report BAC in units of mg/dL or mmol/L. In legal cases, results are reported in percentage (grams of ethyl alcohol per 100 mL of whole blood). If the diagnosis is unclear, if the intoxication seems atypical, or when there is suspicion of multiple drug ingestions, a complete toxicologic screen to rule out the presence of other substances may be useful.

### CLINICAL PRESENTATION OF ALCOHOL INTOXICATION AND WITHDRAWAL

#### General

- Acute alcohol detoxification and withdrawal after chronic alcohol abuse is a serious condition that can require hospitalization and adjunctive pharmacotherapy. If the BAC gets high enough, death is possible.

#### Symptoms

- The intoxicated patient can present with slurred speech and ataxia. The patient can be sedated or unconscious. As BACs decrease rapidly, nausea, vomiting, and hallucinations can ensue. Delirium and seizures are the most severe symptoms.

#### Signs

- The intoxicated patient can present with nystagmus.
- In withdrawal, the patient can present with tachycardia, diaphoresis, or hyperthermia.

#### Laboratory Tests

- In the emergency department, a BAC should be ordered when alcohol ingestion is suspected. Most laboratories report BAC in units of milligrams per deciliter. A whole blood alcohol level of 150 mg/dL (33 mmol/L) reported in the hospital corresponds to 0.15% BAC obtained by law enforcement.
- A complete toxicologic screen to rule out the presence of other substances can be useful.

#### Other Diagnostic Tests

- Differentiate acute alcohol intoxication from other medical illnesses (e.g., head trauma).
- Use computed tomography (CT) on any patient with focal neurologic findings, failure to improve, new-onset seizures, or mental status out of proportion to degree of intoxication.

ALCOHOL-RELATED DISORDERS

Alcohol Withdrawal

Goals for alcohol-dependent persons trying to decrease or discontinue alcohol intake include: (1) the prevention and treatment of withdrawal symptoms (including seizures and delirium tremens) and medical or psychiatric complications, (2) long-term abstinence after detoxification, and (3) entry into ongoing medical and alcohol-dependence treatment.

PHARMACOLOGIC THERAPY

Symptom-triggered treatment with a benzodiazepine is the current standard of care in alcohol detoxification to manage and minimize symptoms and avoid progression to the more severe stages of withdrawal. A meta-analysis was performed to provide evidence-based recommendations on the pharmacologic management of alcohol withdrawal20 and alcohol withdrawal delirium.21 Trials comparing different benzodiazepines demonstrated that all appear similarly efficacious in reducing signs and symptoms of withdrawal.20,21 Lorazepam is preferred by many clinicians because it can be administered intravenously, intramuscularly, or orally with predictable results. Another consideration in the choice of benzodiazepines is their potential for abuse during recovery. A Cochrane Review22 of the effectiveness and safety of benzodiazepines in the treatment of alcohol withdrawal symptoms was published in 2005. According to this report: “the available data show that benzodiazepines are effective against alcohol withdrawal seizures when compared to placebo. However, there are no prominent differences between benzodiazepines and other drugs in success rates. Data on safety outcomes are sparse and fragmented. There is a need for larger, well-designed studies in this field.”

Treatment Regimens

Symptom-Triggered Therapy With symptom-triggered therapy, medication is given only when the patient has symptoms. This approach results in treatment that is shorter, potentially avoiding over sedation and allowing the clinician to focus on specific therapy for alcohol dependence.20,21 A typical regimen would include lorazepam 2 mg administered every hour as needed when a structured assessment scale—such as the Clinical Institute Withdrawal Assessment—Alcohol, Revised—indicates that symptoms are moderate to severe (Table 75–3).21

CBC, complete blood count; CIWA-Ar, Clinical Institute Withdrawal Assessment for Alcohol, revised; D5, dextrose 5%; KCl, potassium chloride; NS, normal saline; WBC, white blood cell count.

Strength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple-time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from Mayo-Smith20,21 Mayo-Smith et al22.
Fixed-Schedule Therapy Over the years, benzodiazepines given regularly at a fixed dosing interval have been used for alcohol withdrawal. The major problem with this approach is underdosing of the benzodiazepine because of the phenomenon of cross-tolerance (see Table 75–3). Current guidelines take exception with this rigid approach, urging clinicians to allow for some degree of individualization within fixed-schedule therapy.

Treatment of Alcohol Withdrawal Seizures

Alcohol withdrawal seizures do not require treatment with an anticonvulsant drug unless they progress to status epilepticus because seizures usually end before diazepam or another drug can be administered. Phenytoin, which is not cross-tolerant to alcohol, does not prevent or treat withdrawal seizures, and without an intravenous loading dose, therapeutic blood levels of phenytoin are not reached until acute withdrawal is complete. Patients experiencing seizures should be treated supportively. An increase in the dosage and slowing of the tapering schedule of the benzodiazepine used in detoxification or a single injection of a benzodiazepine can be necessary to prevent further seizure activity. Patients with a history of withdrawal seizures can be predicted to experience an especially severe withdrawal syndrome. In such patients, a higher initial dosage of a benzodiazepine and a slower tapering period of 7 to 10 days are advisable.

Treatment of Nutritional Deficits and Electrolyte Abnormalities

Fluid status should be carefully assessed, and fluid, electrolyte, and vitamin abnormalities should be corrected. Hydration can be necessary in patients with vomiting, diarrhea, increased body temperature, or severe agitation. Alcoholics often have electrolyte imbalances because of inadequate nutrition and fluid volume related to antidiuretic hormone inhibition. Hypokalemia can be corrected with oral potassium supplementation as long as renal function is adequate. Hypophosphatemia is common but should be allowed to gradually correct with adequate nutrition if phosphorus levels are greater than 1 mg/dL (0.32 mmol/L). Hypomagnesemia is also common, but routine magnesium replacement for alcohol withdrawal is not recommended. Thiamine (vitamin B1) is often depleted in alcoholics, particularly those with poor nutrition. Thiamine supplementation is standard because it can prevent the development of the Wernicke-Korsakoff syndrome (e.g., mental confusion, eye movement disorders, and ataxia [poor motor coordination]), which may not be reversible once it develops. An initial dose of 100 mg IV or IM is commonly used. In practice, thiamine is usually given 100 mg once daily orally, intravenously, or intramuscularly for 3 to 5 days. It is not necessary for thiamine to be continued empirically for longer than 5 days (see Table 75–3).

Other nutritional deficits can also occur with chronic alcohol abuse primarily caused by poor eating habits. A multivitamin is usually given once daily. If clotting factors are abnormal because of decreased liver function and a relative inability to produce vitamin K–dependent clotting factors, then 2.5 to 25 mg of vitamin K can also be prescribed.

Alcohol hypoglycemia usually occurs in the absence of overt liver disease, and it is more likely if the patient is fasting or exercising or is sensitive to alcohol; it is less likely if the patient is obese. The alcohol directly interferes with hepatic gluconeogenesis but not glycolysis. The energy required for metabolism of alcohol is diverted away from the energy needed to take up lactate and pyruvate—substrates for gluconeogenesis. So, patients who drink alcohol can become hypoglycemic once glycogen stores are depleted. Neurologic symptoms of hypoglycemia can be confused with alcohol intoxication, and in the inpatient setting, blood glucose should be monitored regularly.

Treatment Settings

Alcohol withdrawal treatment can take place in hospitals, inpatient detoxification units, or outpatient settings. Inpatient treatment can be necessary when there are coexisting acute or chronic medical (including pregnancy), surgical, or psychiatric conditions that would complicate alcohol withdrawal. Only patients with mild to moderate symptoms should be considered for outpatient treatment, and it is a good idea to have a responsible, sober person available to help the patient monitor symptoms and administer medications. Patients with a strong craving for alcohol, those concurrently using other drugs, and those with a history of seizures or delirium tremens are not good candidates for outpatient treatment. Pharmacologic agents used in the treatment of alcohol withdrawal are summarized in Table 75–3.

PHARMACOLOGIC MANAGEMENT OF ALCOHOL DEPENDENCE

In the United States, disulfiram, naltrexone, the once-monthly injectable extended-release naltrexone, and acamprosate are the only four drugs that are FDA-approved for the treatment of alcohol dependence. Disulfiram acts as a deterrent to the resumption of drinking, and naltrexone is a competitive opioid antagonist that has been shown to reduce cravings for alcohol. Acamprosate is a GABA-ergic agonist that modulates alcohol cravings (Table 75–4). Other drugs, including nalmefene, bupropion, various serotonergic

*Strength of recommendations: A = good, moderate, and poor evidence to support recommendation, respectively.
Quality of evidence: 1 = evidence from more than 1 properly randomized, controlled trial; 2 = evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple-time series; or dramatic results from uncontrolled experiments; 3 = evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.
Data from Boothby and Doering@. Caruthet et al.18a.
agents (including selective serotonin reuptake inhibitors and vascular serotonin 5-HT  receptor antagonists), topiramate, and lithium also have been used either abroad or in the United States off-label for alcohol dependence. A recent meta-analysis24 has been published with the primary objective of completing the efficacy profiles for acamprosate and naltrexone by contacting researchers when outcomes were missing and to compare them with each other. Naltrexone was found to have a significant effect on the maintenance of abstinence as well as the prevention of heavy drinking. Acamprosate was shown only to support abstinence; it did not influence alcohol consumption after the first drink. When the efficacy profiles of the two drugs were compared, acamprosate was found to be more effective in preventing a lapse, whereas naltrexone was better in preventing a lapse from becoming a relapse.

**CLINICAL CONTROVERSY**

The most difficult clinical problem in the treatment of alcohol-related illness is helping patients remain abstinent after alcohol detoxification. Acamprosate and naltrexone have been shown to be superior to nonpharmacologic therapy alone for maintenance of abstinence from alcohol; however, relapse during naltrexone and acamprosate therapy is still common. Disulfiram use has fallen out of favor. Studies have failed to prove it effective, and it is poorly tolerated. For this reason, most clinicians rarely recommend the use of disulfiram.

**DISULFIRAM**

Disulfiram deters a patient from drinking by producing an aversive reaction if the patient drinks. In the absence of alcohol, disulfiram has minimal effects. Disulfiram inhibits the liver enzyme aldehyde dehydrogenase in the biochemical pathway for alcohol metabolism, allowing acetaldehyde to accumulate. The resulting increase in acetaldehyde causes severe facial flushing, throbbing headache, nausea and vomiting, chest pain, palpitations, tachycardia, weakness, dizziness, blurred vision, confusion, and hypotension. Severe reactions including myocardial infarction, congestive heart failure, cardiac arrhythmia, respiratory depression, convulsions, and death can occur, particularly in vulnerable individuals. A recent review summarizes disulfiram’s overall usefulness.25

**NALTREXONE**

Naltrexone, an opiate antagonist available in the United States since 1984 for the treatment of opioid dependence blocks the effects of exogenous opioids. In 1994, the FDA approved its use in the treatment of alcohol dependence. Naltrexone is thought to attenuate the reinforcing effects of alcohol, and those who consume alcohol while taking naltrexone report feeling less intoxicated and having less craving for alcohol.25

Short-term treatment (up to 12 weeks) with naltrexone decreases the chance of alcohol relapse by 36% versus placebo.29 Naltrexone should not be given to patients currently dependent on opioids because it can precipitate a severe withdrawal syndrome. Naltrexone is associated with dose-related hepatotoxicity, but this generally occurs at doses higher than those recommended for treatment of alcohol dependence. Nevertheless, it is considered contraindicated in patients with hepatitis or liver failure, and liver function tests should be monitored monthly for the first 3 months and every 3 months thereafter.

Nausea is the most common side effect of naltrexone, occurring in approximately 10% of patients. Other side effects are headache, dizziness, nervousness, fatigue, insomnia, vomiting, anxiety, and somnolence. If dosed daily, naltrexone 50 mg per day is sufficient to effectively block μ-opioid receptors.

In April 2006, the FDA approved Vivitrol, a once-monthly intramuscular naltrexone formulation. The usual effective dose is 380 mg IM each month.25,26 Extended release formulations reduce the likelihood of forgetting or choosing not to take medication, assuring that once the patient receives an injection, he or she will be “adherent” for the next month.26

**ACAMPROSATE**

Acamprosate is a glutamate modulator at the N-methyl-D-aspartate (NMDA) receptor that reduces alcohol craving. Acamprosate, approved in the United States in 2004, had been available in Europe for many years. Patients treated with acamprosate are more successful in maintaining abstinence from alcohol versus placebo. In addition, the combination of acamprosate and naltrexone has been shown to be more efficacious than acamprosate alone for the maintenance of abstinence from alcohol, when combined with psychosocial interventions. Acamprosate is well tolerated, with gastrointestinal adverse effects most common.27 See Table 75–4 for dosing information for this and the other options used in treating alcohol dependence.

**NICOTINE**

Cigarette smoking is an enormous national health problem, and as healthcare professionals, we all must continue to work to help people to quit smoking. Clinical guidelines for tobacco use and dependence were released in 2000, which stressed the importance of healthcare professionals screening each patient for tobacco use.24 In 2008, the clinical guidelines were updated, and many more patients are now counseled on the importance of smoking cessation. Telephone quit lines are now available in every state, and more patients are referred to smoking cessation counseling services. Additionally, more patients have access to FDA-approved medications for smoking cessation through private insurance or Medicaid compared to a decade ago.28

Despite this encouraging news, cigarette smoking continues to be the leading cause of preventable morbidity and mortality in the United States. When the CDC analyzed the data from the 2008 National Health Interview Survey (NHIS) it was found that the number of current smokers from the years 1998 to 2008 did decrease by 3.5%, but the proportion of current smokers from 2007 to 2008 did not change.29 All healthcare providers should screen patients and utilize the clinical guidelines for tobacco use and dependence once a smoker is identified.28

**EPIDEMIOLOGY OF TOBACCO USE**

The National Survey on Drug Use and Health reported in 2007 that an estimated 28.6% (70.9 million) of the U.S. population 12 years of age and older used a tobacco product at least once in the month prior to being interviewed. Each day, about 1,000 persons younger than 18 years of age become regular smokers, and it is now estimated 20% (43.8 million) of high school students currently smoke on a regular basis.30 In addition, 60 million Americans were current cigarette smokers, 13.3 million smoked cigars, 8.1 million used smokeless tobacco, and 2 million smoked pipes.30 Data trends from the 2008 NHIS showed smoking prevalence did vary based on the level of education one had completed. The highest percentage of adults who admitted to smoking were adults who had earned a General Education Development certificate (41.3%). Those with a graduate level of education reported the lowest percentage of smoking (5.7%).29
The NHIS survey also found that 31.5% of adults currently living under the federal poverty level were current smokers in comparison with the 19.6% of smokers living above the federal poverty level.29

ECONOMIC IMPACT OF SMOKING

The direct healthcare expenditures associated with smoking total more than $96 billion per year, and the costs associated with lost productivity are estimated to be $97 billion. Smoking-attributable medical expenditures31 in the adult Medicaid population total $22 billion, which is estimated as 11% of Medicaid program expenditures.32 It has been calculated that if all Medicaid patients stopped smoking, the annual savings would reach $9.7 billion after 5 years.28

HEALTH RISKS OF SMOKING

Cigarette smoking substantially increases the risk of (1) cardiovascular diseases such as stroke, sudden death, and heart attack; (2) nonmalignant respiratory diseases including emphysema, asthma, chronic bronchitis, and chronic obstructive pulmonary disease; (3) lung cancer; and (4) other cancers.33 Exposure to environmental tobacco smoke (passive exposure) has been cited as the cause of 3,400 lung cancer deaths and 46,000 heart disease-related deaths in the United States every year.34 Children who are exposed to environmental smoke have a higher risk of respiratory infection, asthma, and middle ear infections than those who are not exposed. Sudden infant death syndrome occurs more often in infants whose mothers smoked during pregnancy than in offspring of nonsmoking mothers.34 The harmful effects of smoking on reproduction and pregnancy include reduced fertility and fetal growth, as well as increased risk of ectopic pregnancy and spontaneous abortion.34

PHARMACOLOGY OF NICOTINE

Nicotine is a ganglionic cholinergic agonist with pharmacologic effects that are highly dependent on dose. These effects include central and peripheral nervous system stimulation and depression, respiratory stimulation, skeletal muscle relaxation, catecholamine release by the adrenal medulla, peripheral vasoconstriction, and increased blood pressure, heart rate, cardiac output, and oxygen consumption. Cigarette smoking or low doses of nicotine produce an increased alertness and increased cognitive functioning by stimulating the cerebral cortex. At higher doses, nicotine stimulates the “reward” center in the limbic system of the brain.35

When nicotine is ingested a feeling of pleasure and relaxation can occur. Repetitive exposure to nicotine leads to neuroadaptation which builds tolerance to the initial effects. An accumulation of nicotine in the body leads to a more substantial withdrawal reaction if cessation is attempted.36 Common symptoms experienced during withdrawal can include anxiety, difficulties concentrating, irritability, and strong cravings for tobacco. Onset of these withdrawal symptoms usually occurs within 24 hours and can last for days, weeks, or longer.36

CLINICAL PRESENTATION OF NICOTINE WITHDRAWAL

General
- The patient may experience anxiety but may not be in acute distress. Symptoms can wax and wane over time.

Symptoms
- The patient may complain of cravings, difficulty concentrating, frustration, irritability, and impatience. Hostility, insomnia, and restlessness can also occur.

Signs
- Increased skin temperature can be present.

TREATMENT

Nicotine Dependence

AGENCY FOR HEALTHCARE RESEARCH AND QUALITY CLINICAL PRACTICE GUIDELINE: TREATING TOBACCO USE AND DEPENDENCE

The Agency for Healthcare Research and Quality (AHRQ) periodically convenes expert panels to develop clinical guidelines for healthcare practitioners. Because of the widespread prevalence of smoking-related illnesses, its related morbidity and mortality, and the economic burden imposed, the agency convened a panel of experts in 1994 to develop guidelines on the treatment of tobacco addiction. The resultant guideline for smoking cessation was released in 1996. In May 2008, an updated version of the 1996 Smoking Cessation Clinical Practice Guideline was issued by AHRQ.28

The revised guideline suggests strategies for providing appropriate treatments for every patient. The panel reminds us that effective treatments for tobacco dependence now exist and that every patient should receive at least minimal treatment every time he or she visits a clinician (Figs. 75–1 and 75–2).

The guideline identified a number of key findings that clinicians should use:

1. Tobacco dependence is a chronic condition that often requires repeated intervention. However, effective treatments exist that can produce long-term or permanent abstinence.
2. Because effective tobacco dependence treatments are available, every patient who uses tobacco should be offered at least one of these treatments:
   - Patients willing to try to quit tobacco use should be provided with treatments that are identified as effective in the guideline.
   - Patients unwilling to try to quit tobacco use should be provided with a brief intervention that is designed to increase their motivation to quit.
3. It is essential that clinicians and healthcare delivery systems (including administrators, insurers, and purchasers) institutionalize the consistent identification, documentation, and treatment of every tobacco user who is seen in a healthcare setting.
4. Brief tobacco dependence treatment is effective, and every patient who uses tobacco should be offered at least brief treatment.
5. There is a strong dose-response relationship between the intensity of tobacco dependence counseling and its effectiveness. Treatments involving person-to-person contact (via individual, group, or proactive telephone counseling) are consistently effective, and their effectiveness increases with treatment intensity (e.g., minutes of contact).
6. Three types of counseling and behavioral therapies were found to be especially effective and should be used with all patients who are attempting tobacco cessation:

- Provision of practical counseling (problem-solving/skills training)
- Provision of social support as part of treatment (intratreatment social support)
- Help in securing social support outside treatment (extratreatment social support)

Numerous effective pharmacotherapy options for smoking cessation now exist (Table 75–5). Seven first-line pharmacotherapy options reliably increase long-term smoking abstinence rates: sustained-release (SR) bupropion, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch, and varenicline. Combinations of these should be considered if a single agent has failed.

Two second-line pharmacotherapy options are considered efficacious and can be considered by clinicians if first-line options are not effective: clonidine and nortriptyline.

Tobacco-dependence treatments are both clinically effective and cost-effective relative to other medical and disease prevention interventions. As such, insurers and purchasers should ensure all insurance plans include a reimbursed benefit the counseling and pharmacotherapeutic treatments that are identified as effective in this guideline, as well as clinician reimbursement for providing tobacco dependence treatment just as they are reimbursed for treating other chronic conditions.

OTHER FACTORS IMPORTANT TO THE SUCCESS OF A SMOKING-CESSATION STRATEGY

The AHRQ expert panel emphasized the importance of the type and intensity of the contact with the counselor to the success of the intervention. When interventions last for more than 10 minutes, the increase in cessation rates is much better than when interventions do not involve contact with a professional. Group and individual counseling is more effective than no intervention in increasing abstinence rates. Self-help materials (e.g., handouts, pamphlets, and brochures) without any direct physical contact are not effective. Interventions are more successful when they include social support and training in general problem-solving skills, stress management, and relapse prevention. The number of treatment sessions offered is also important. Providing at least four or more sessions, longer than 10 minutes in length, and if possible providing treatments from multiple types of clinicians have proven higher success rates compared to less intensive interventions. Although comprehensive behavioral interventions have been shown to be more effective in helping people quit smoking and remain abstinent, less intensive treatments are beneficial as well. Even minimal contacts lasting less than 3 minutes and simple advice to quit are more successful in increasing cessation rates than intervention involving no contact.

Counseling alone can be effective, but counseling efficacy is further augmented by the addition of pharmacotherapy. In a meta-analysis which included 111 trials with more than 43,000 participants using one or more of the five forms of nicotine replacement therapy (NRT) including nicotine gum, nasal spray, patches,
lozenges, or inhaler, it was found the use of NRT led to a significant rate of cessation compared to the cessation rates with placebo.\textsuperscript{38}

Although comprehensive programs are most effective, few smokers (10%–15%) seek formal assistance in quitting.\textsuperscript{28}

\section{Pharmacologic Therapy for Smoking Cessation}

All patients attempting to quit should be encouraged to use effective pharmacotheraphy agents for smoking cessation except in the presence of special circumstances. Long-term smoking-cessation pharmacotherapy should be considered as a strategy to reduce the likelihood of relapse. As with other chronic diseases, the most effective treatment of tobacco dependence encompasses multiple modalities. Pharmacotherapy is a vital element of a multicomponent smoking cessation program that should also always include nonpharmacologic components. The clinician should encourage all patients initiating a quit attempt to use one or a combination of efficacious pharmacotherapy agents, although pharmacotherapy use requires special consideration with some patient groups (e.g., those with medical contraindications, those smoking fewer than 10 cigarettes a day, pregnant or breast-feeding women, and adolescent smokers). The role of pharmacotherapy in smoking cessation is summarized in Table 75-5.

\section{Nicotine-Replacement Therapy}

\subsection{A Systematic Review of Nicotine Replacement Therapy}

In 2009, a systematic review\textsuperscript{38} of published studies was performed to determine the effectiveness of the different forms of NRT (e.g., chewing gum, transdermal patches, nasal spray, inhalers, and tablets) in achieving abstinence from cigarettes or a sustained reduction in the amount smoked. The review was also designed to determine whether the effect is influenced by the clinical setting in which the smoker is recruited and treated, the dosage and form of the NRT used, or the intensity of additional advice and support offered to the smoker; to determine whether combinations of NRT are more effective than one type alone; and to determine its effectiveness compared to other pharmacotherapy agents.

The review was limited to randomized trials in which NRT was compared to placebo or no treatment, or where different doses of NRT were compared. The main outcome measure was abstinence from smoking after at least 6 months of follow-up. For each trial, researchers used the most rigorous definition of abstinence, and confirmation with biochemical markers where available. The review includes 132 studies, 111 of which included a placebo or non-nicotine control arm. All of the commercially available forms of NRT were effective for smoking cessation. Use of NRT doubled the odds of quitting. Higher doses of nicotine patch can produce additional small increases in quit rates compared to lower doses. Only one study directly compared NRT to another pharmacotherapy, in which bupropion was significantly more effective than nicotine patch or placebo.\textsuperscript{38}

In late 2009, the first head-to-head placebo-controlled trial comparing five smoking cessation pharmacotherapies with 1,504 smokers who had smoked at least 10 cigarettes per day for 6 months and who were interested in achieving cessation was published. Patients were randomized to receive SR bupropion, nicotine patch, nicotine lozenge, nicotine patch plus nicotine lozenge, bupropion plus nicotine lozenge, or placebo. The patients were required to use the assigned NRT plus attend six 10 to 20 minute individual counseling sessions. Two of the counseling sessions were held prior to beginning NRT, the second on the actual quit date. The other counseling sessions were then scheduled on weeks 1, 2, 4, and 8 from the quit date. Abstinence was confirmed by using blood tests to determine

LOE, level of evidence.

\textsuperscript{a}Nicotine replacement therapies can be combined with each other and/or bupropion to increase long-term abstinence rates.

\textsuperscript{b}Do not abruptly discontinue. Taper up initially, and taper off once therapy is complete.

\textsuperscript{c}Clonidine and nortriptyline are not FDA-approved for smoking cessation.

\textsuperscript{d}Strength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series; or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Data from U.S. Department of Health and Human Services.\textsuperscript{26,34}
carbon monoxide. At 6 months it was found the quit rates were 40.1% for the nicotine patch plus nicotine lozenge, 34.4% for the nicotine patch, 33.5% for the nicotine lozenge, 33.2% for bupropion plus nicotine lozenge, 31.8% for bupropion alone, and 22.2% for placebo. It was postulated that the nicotine patch provided a stable blood level of nicotine in the blood to aid with withdrawal but the addition of the nicotine lozenge allowed for coverage during intense craving periods to decrease the chances of relapse.36

The AHRQ guidelines recommend use of NRT in the forms of transdermal nicotine patches, nicotine gum, nicotine sprays, nicotine inhalers, and nicotine lozenges.28 Although cardiovascular disease is not an independent risk factor for acute myocardial events in patients taking NRT, NRT should be used with caution among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post–myocardial infarction period, those with serious arrhythmias, and those with serious or worsening angina pectoris.28

Nicotine Gum

Clinicians should offer 4-mg rather than 2-mg nicotine gum to highly dependent smokers.28 The 2-mg gum is recommended for patients smoking fewer than 25 cigarettes per day, whereas the 4-mg gum is recommended for patients smoking 25 or more cigarettes per day. Generally, the gum should be used for up to 12 weeks, no more than 24 pieces chewed per day. The dosage and duration of therapy should be tailored to meet the needs of each patient.

Nicotine gum currently is available exclusively as an over-the-counter medication and is packaged with important instructions on correct use, including chewing instructions. There is currently little evidence to suggest that combined use of the patch and gum increases abstinence beyond 24 weeks.

Gum should be chewed slowly until a peppery or minty taste emerges and then “parked” between cheek and gums to facilitate nicotine absorption through the oral mucosa. It should be chewed slowly and intermittently and parked for about 30 minutes or until the taste dissipates. Acidic beverages (e.g., coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing. Patients often do not use enough gum to get the maximum benefit: they chew too few pieces per day, and they might not use the gum for a sufficient number of weeks. Instructions to chew the gum on a fixed schedule (at least one piece every 1–2 hours) for at least 1 to 3 months can be more beneficial than ad libitum use.

Nicotine Patch

The nicotine patch is available both as an over-the-counter medication and as a prescription drug and it approximately doubles long-term abstinence rates over those produced by placebo interventions.28 Treatment of 8 weeks or less has been shown to be as efficacious as longer treatment periods. The 16- and 24-hour patches are of comparable efficacy.33 Clinicians should consider starting treatment on a lower patch dose in patients smoking 10 or fewer cigarettes per day.28

A patch should be applied as soon as the patient wakes on the quit day and at the start of each day thereafter. The patient should place a new patch on a relatively hairless location, typically between the neck and waist. There are no restrictions on activity while using the patch. Patients who experience sleep disruption should remove the 24-hour patch prior to bedtime or use the 16-hour patch.

Nicotine Nasal Spray

Nicotine nasal spray more than doubles long-term abstinence rates when compared with a placebo spray. Nicotine nasal spray is available exclusively as a prescription medication. A dose of nicotine nasal spray consists of one 0.5-mg delivery to each nostril (1 mg total). Initial dosing should be one to two doses per hour, increasing as needed for symptom relief. The minimum recommended treatment is 8 doses per day, with a maximum limit of 40 doses per day (5 doses per hour). Each bottle contains approximately 100 doses. Recommended duration of therapy is 3 to 6 months. Patients should not sniff, swallow, or inhale through the nose while administering doses because this increases irritant effects.

Nicotine Lozenge

The nicotine lozenge is available as a 2-mg and a 4-mg dose. The 2-mg lozenge is recommended for patients who normally smoke their first cigarette later than 30 minutes after awakening, and the 4-mg lozenge is recommended for smokers who smoke within 30 minutes of waking. It is recommended that patients use at least nine lozenges daily the first 6 weeks of therapy. The duration of treatment is 12 weeks. It is recommended no more than 20 lozenges should be used in 1 day.28 In comparison to the nicotine gum, nicotine release is more controlled and does not depend on the correct “chew and park” method required by the gum. The most common side effect of the lozenge is nausea. As with the nicotine gum, acidic beverages (e.g., coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during use of the lozenge.28

Instructing Patients in the Use of NRT

Compliance with NRT improves when the patient is presented a clear rationale for its use and a realistic expectation about the response. It should be explained to the patient that nicotine is responsible for addiction and that discontinuation of the nicotine causes craving for cigarettes, tension, irritability, sadness, problems with sleep, and difficulty concentrating. These are partly due to nicotine withdrawal. The patient should be told that using the patch results in less desire to smoke and provides an opportunity for a new nonsmoker to practice all the new nonsmoking skills without being burdened by craving. The patient should understand that with smoking, there are naturally peaks and valleys in the amount of nicotine in the bloodstream. With the patch there is a steady gradual rise in the blood nicotine concentration that levels off and remains constant for much of the day and then gradually decreases while the person is asleep. Maintaining an adequate blood level of nicotine lessens withdrawal symptoms.

A similar rationale can be used if patients are using gum. It should be emphasized that NRT is not a “magic bullet” and that the use of coping skills is essential for abstinence. The patch or the gum only buys time by reducing withdrawal symptoms and giving individuals a chance to figure out alternatives that they can use in place of smoking.28

### CLINICAL CONTROVERSY

Some clinicians are hesitant to prescribe nicotine replacement therapy for smoking cessation during pregnancy because the safety and efficacy of nicotine replacement therapy has not been established in controlled clinical trials in this population. This logic is somewhat counterintuitive in that continued smoking exposes the unborn child to much higher levels of nicotine, and the harmful consequences of cigarette smoking during pregnancy are well documented.
Side Effects
Nicotine replacement products have relatively few side effects. Nausea and light-headedness are possible symptoms of nicotine overdose that warrant a reduction of the nicotine dose.

The most frequent side effect with the nicotine patch is skin irritation related to the adhesive or the medium containing nicotine and not to the nicotine itself. Approximately 50% of patients report skin irritation during the course of treatment with the patch. The patch site can be rotated to diminish this problem. The use of over-the-counter hydrocortisone cream (1%) or triamcinolone cream (0.5%) is recommended as a local treatment for patch-related skin irritations. Switching to a different brand of patch also can alleviate the problem because different products use different adhesives or media. The gum can be used instead of the patch when the skin irritation is severe. Less than 5% of patients were forced to discontinue therapy because of skin reactions.

Approximately 23% of patients using the patch report sleep disturbances, but the insomnia is hard to differentiate from the sleeplessness that often accompanies withdrawal itself, especially during the first few weeks of quitting.

Duration
Those who commit to quitting smoking using nicotine replacement should be told that treatment for up to three months is common. However, some patients will experience severe withdrawal even beyond this time period so long term use of NRT might be indicated. Long term use of NRT has not been linked to any safety concerns and is supported by the 2008 updated U.S. Public Health Service Guidelines.

Economic and Pharmacoeconomic Considerations
Most health insurers provide coverage for the chronic illnesses caused by smoking (e.g., chronic obstructive pulmonary disease, cancer, and myocardial infarction), yet few provide coverage for treating the nicotine addiction that caused those ailments. The U.S. Public Health Service’s Clinical Practice Guideline on Treating Tobacco Use and Dependence Update 2008 strongly encourages a comprehensive treatment plan for smoking cessation which includes both use of the recommended pharmacotherapy agents and extensive counseling. It has been shown if a comprehensive smoking cessation program is a paid or covered health benefit within the insurance plan an increased success rate for cessation is seen. In 2006 it was estimated that 35% of Medicaid recipients smoked cigarettes but the current coverage of smoking cessation pharmacotherapy agents as well as counseling sessions are still very limited, and availability is inconsistent with the current federal clinical guidelines. Accounting for direct healthcare expenditures and productivity losses (approximately $97 billion per year), the total economic burden of smoking is approximately $193 billion per year. The CDC reports $203.9 billion was available to states from the years 2000 to 2009 from tobacco taxes and legal settlements. An investment of only 15% of these funds the states received on an annual basis would have funded every state tobacco control program. Unfortunately, it has been reported that states spent less than 3% on any tobacco prevention and cessation programs. Expanding coverage of not only the pharmacotherapy agents available for smoking cessation but the reimbursement for counseling as recommended by the updated guidelines by the health insurers and by Medicaid programs is imperative to improve smoking abstinence rates.

NON-NICOTINE OPTIONS
Bupropion
Bupropion inhibits neuronal reuptake and potentiates the effects of norepinephrine and dopamine. Although its precise mechanism in smoking cessation is not well understood, dopamine has been associated with the rewarding effects of addictive substances. Withdrawal symptoms can be decreased by virtue of bupropion inhibition of norepinephrine uptake. The AHRQ panel concluded that SR bupropion is an efficacious smoking cessation treatment that patients should be encouraged to use. Contraindications for bupropion use include current or past seizure disorders, a history of monoamine oxidase inhibitor use over the last 14 days, and a history of anorexia nervosa or bulimia. Along with multiple other precautions listed in the product labeling, current alcohol use, use of medications which lower seizure threshold (e.g., antidepressants, antipsychotics), and depression are possible concerns when using this medication. In 2009, the FDA started requiring the manufacturers of Zyban (bupropion) and generic manufacturers to add new black box warnings and develop a medication guide highlighting the risk of serious neuropsychiatric symptoms in patients using this product. Possible symptoms include depressed mood, agitation, anxiety, hostility, changes in behavior, suicidal thoughts and behavior, and attempted suicide.

A double-blind, placebo-controlled, randomized multicenter trial was conducted in which healthy smokers were randomized to receive either SR bupropion 150 mg twice daily or a placebo daily for 7 weeks and subsequently seen for counseling and follow-up for a total of 52 weeks. The primary end points were biochemically confirmed continuous abstinence at weeks 7 and 52. The authors specifically conducted this trial in the primary care setting to verify the general applicability of the results to the intended end users. While similar studies have been performed in academic settings and have shown favorable results, the authors contend the real therapeutic potential or impact of a pharmacologic approach to smoking cessation must be evaluated by general practitioners in the primary care setting. They further assert that the approach should address healthy smokers and use continuous abstinence at week 52 as the most valid outcome measure. The results of this study showed bupropion was efficacious, with an absolute 25% of participants continuously abstinent at 1 year; it doubled the odds of continuous abstinence from week 4 to week 7 and from week 4 to week 52 compared with placebo.

A recent meta-analysis was conducted by the Cochrane Collaboration involving 49 trials utilizing bupropion for smoking cessation. Bupropion was shown to significantly increase the incidence of long-term cessation when used as a sole agent in 36 separate trials. Other trials which used bupropion as an add-on agent with NRT did not show additional benefit for improving cessation rates. The incidence of seizures was fairly low when considering the use continuous abstinence at week 52 as the most valid outcome measure. The results of this study showed bupropion was efficacious, with an absolute 25% of participants continuously abstinent at 1 year; it doubled the odds of continuous abstinence from week 4 to week 7 and from week 4 to week 52 compared with placebo.

Varenicline (Chantix)
Varenicline, a new and novel aid to smoking cessation, was approved by the FDA in 2006. It acts at sites in the nicotine-affected brain in two ways: by providing nicotine effects to ease withdrawal...
symptoms and by blocking the effects of nicotine from cigarettes if they resume smoking. Specifically, varenicline is a partial agonist that binds selectively to $\alpha_2\beta_2$-nicotinic acetylcholine receptors with a greater affinity than nicotine. When bound to the receptor, the drug blocks nicotine from binding and also evokes a response but to a lesser degree than nicotine. The stimulation of the receptor results in release of dopamine and thus provides a type of “reward” that can decrease craving and withdrawal symptoms.\(^{47}\)

The recommended dosage for varenicline is 0.5 mg daily for 3 days, increase to 0.5 mg twice daily for 3 days, and then increase to 1 mg twice daily for a standard 12-week treatment. If abstinence has not been achieved after the 12-week treatment, then a second 12-week treatment may be prescribed.\(^{44}\)

Varenicline is listed as a first-line agent in the updated clinical guidelines on treating tobacco use and dependence. Seven trials comparing varenicline with placebo, three of which also had a comparison with bupropion, were reviewed in a recent Cochrane Review meta-analysis. Varenicline caused a two- to three-fold increased likelihood of long-term smoking cessation compared with placebo. It was also found that varenicline’s rate of cessation was greater than that of bupropion.\(^{45}\)

Since 2006, when varenicline was approved by the FDA, alarming numbers of adverse effects including suicidal thoughts, erratic behavior, and aggressive behavior have been reported. The large number of reports led to the release of a Public Health Advisory by the FDA in February 2008.\(^{46}\) The advisory stressed the importance of screening for any type of psychiatric illness or any behavior changes after starting varenicline. A boxed warning along with an update of the medication guide from the manufacturer was required by the FDA.\(^{46}\) Specific warnings stress that patients should report any history of psychiatric illness and any changes in behavior or mood immediately to their prescribing practitioner. Impairment of the ability to drive or operate heavy machinery and the possibility of strange or vivid dreams are also stressed in the medication guide.\(^{46}\)

**SECOND-LINE MEDICATIONS**

Second-line medications are pharmacotherapies for which there is evidence of efficacy for treating tobacco dependence, but which have a more limited role than first-line medications because (1) the FDA has not approved them for a tobacco-dependence treatment indication, and (2) there are more concerns about potential side effects than exist with first-line medications.\(^{28}\) Second-line treatments should be considered for use on a case-by-case basis after first-line treatments have been used or considered.

**Clonidine**

Clonidine has been found to be efficacious as a smoking cessation treatment, although its only labeled indication is for treatment for hypertension. It can be used off-label as a second-line agent to treat tobacco dependence. A recent meta-analysis of six trials showed that clonidine increased smoking cessation rates by 11% (odds ratio [OR], 1.89; confidence interval [CI], 1.30–2.14). There was a high incidence of dose-dependent side effects, particularly dry mouth and sedation.\(^{47}\) It should be noted that abrupt discontinuation of clonidine can result in symptoms such as nervousness, agitation, headache, and tremor, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine levels.

Doses used in various clinical cessation trials have varied significantly, from 0.15 to 0.75 mg/day orally to 0.1 to 0.2 mg/day transdermally, without a clear dose-response relation to cessation. Initial dosing typically is 0.1 mg orally twice daily or 0.1 mg/day transdermally, increasing by 0.1 mg/day each week if needed. The duration also varied across the clinical trials, ranging from 3 weeks to 12 months. Most commonly reported side effects include dry mouth, drowsiness, dizziness, sedation, and constipation. Clonidine will lower blood pressure in most patients, thus blood pressure should be monitored.\(^{28}\)

**Nortriptyline**

Nortriptyline is also considered to be efficacious as a second-line agent to treat tobacco dependence. It should be considered for smoking cessation under a clinician’s direction in patients unable to use first-line medications because of contraindications and in patients who failed using first-line medications. Therapy is initiated 10 to 28 days before the quit date to allow nortriptyline to reach steady state at the target dose. Smoking cessation trials have initiated treatment at a dose of 25 mg/day, increasing gradually to a target dose of 75 to 100 mg/day. Duration of treatment used in smoking cessation trials has been approximately 12 weeks. Most commonly reported side effects include sedation, dry mouth, blurred vision, urinary retention, light-headedness, and tremor.\(^{28}\)

**Future Treatments**

Work continues on the development of vaccines to be used in treating nicotine addiction. NicVAX (an experimental nicotine conjugate vaccine) is designed to cause the immune system to produce antibodies that bind to nicotine and prevent it from entering the brain. As a result, the positive stimulus in the brain that is normally caused by nicotine is no longer present, thereby taking away the physical motivation for smoking, consequently helping people to quit.\(^{46,49}\)

Results from the phase II clinical studies on 301 patients who were smoking an average of 24 cigarettes a day showed the vaccine “induced the production of a long lasting antibody which helped in the prevention of a smoking relapse for up to 2 months in approximately 25% of the study participants.”\(^{50}\)

---

**CLINICAL PRESENTATION OF EXCESSIVE CAFFEINE INTAKE**

**General**
- The patient may not be in acute distress.

**Symptoms**
- The patient may complain of nausea, vomiting, diarrhea, and psychomotor agitation, and can appear restless, nervous, and excited.

**Signs**
- The patient can present with facial flushing, diuresis, and muscle twitching.
- Tachycardia or cardiac arrhythmias can also occur.

**Laboratory Tests**
- Caffeine serum concentrations are rarely used clinically.

**CAFFEINE**

Caffeine is the most widely consumed behaviorally active substance in the world, generating an increased sense of well-being, happiness, energy, alertness, and sociability.\(^{51}\) Caffeinism is the term coined to describe the clinical syndrome produced by acute or chronic overuse of caffeine. The syndrome usually is characterized by CNS and peripheral manifestations, most notably anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiologic complaints.\(^{52}\)
As many as one in five adults consume doses of caffeine generally considered large enough to cause clinical symptoms.31,32 Pharmacologically, the risk of developing some meaningful clinical manifestations becomes high when intake exceeds 500 mg/day. This places 20% to 30% of North Americans at risk.31 Caffeine has been proposed as a “model of drug abuse” despite the facts that its sale is largely unrestricted and that heavy consumption of caffeine-containing beverages is not considered to be drug abuse. An exhaustive review of caffeine dependence focused on the potential for abuse of caffeine and the nature of tolerance and withdrawal.31 The information below represents a broad overview of these topics, and the reader interested in more detail is urged to consult the review by Juliano and Griffiths.31

**EPIDEMIOLOGY OF CAFFEINE USE AND ABUSE**

Caffeine is used by 80% of the population of the United States. In 1999 there were 108,000,000 coffee consumers in the United States spending approximately $9.2 billion in the retail sector and $8.7 billion in the food service sector every year.32 The National Coffee Association found in 2001 that 52% of the adult population of the United States drinks coffee daily.33 Newer market research data are available but are a closely protected proprietary secret. It is safe to say that in the 10 years since these data were freely available, coffee consumption has likely increased.

The majority of caffeine users progress to a pattern of frequent or daily consumption. Approximately one-fourth eventually begin consuming large quantities, exceeding 500 mg/day, and conservatively, 10% of all adults then progress to develop the syndrome of caffeinism. Mean daily consumption of caffeine in American children is surprisingly high. The Framingham Children’s Study34 investigated the amounts of caffeine consumed each day by children between the ages of 6 and 10 years (mean, 8.4 years for boys and 8.1 years for girls). Mean intake of caffeine was 16 ± 9.6 mg/day. Caffeinated soft drinks and chocolate furnished almost all of the caffeine.35

**ENERGY DRINKS**

In recent years a number of energy drinks containing caffeine, taurine, vitamins, and usually sugar have found their way onto the American market. Sold under brand names such as Red Bull, Monster Energy, Rockstar, and Full Throttle, these products are especially popular with adolescents and emerging adults, with sales exceeding half a million dollars in 2006.36 This represents a more than 50% increase over 2005.36 These products are generally marketed to enhance alertness or providing a short-term energy boost and do not constitute suitable sources of rehydration or restoration of electrolytes in association with athletic activity.36

Additionally, several manufacturers have marketed alcoholic beverages that have caffeine as an additional ingredient. Some may have other stimulant ingredients such as guarana, taurine, and ginseng. The Center for Science in the Public Interest has chosen to call these beverages “alcospeed.”37

**DIFFERENTIAL DIAGNOSIS**

Caffeine intoxication is the only official diagnosis associated with cafainism in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR).3 Caffeine-induced anxiety can manifest as restlessness, nervousness, excitement, insomnia, diuresis, flushing, GI disturbance, muscle twitching, irritability, and jitteriness. If caffeine-induced insomnia requires specific treatment, caffeine-induced sleep disorder is an appropriate DSM-IV-TR diagnosis.3

Because excessive caffeine consumption is so widespread, a thorough history of caffeine use should be included in the routine assessment of all new patients in primary care medical settings. In this manner, the practitioner can use the information gathered to uncover high levels of caffeine intake and then use the information to pinpoint the cause of clinical signs and symptoms typical of cafainism. Clinical manifestations of cafainism almost always will lessen in intensity or disappear completely within 1 to 2 weeks after removing the drug.

**PHARMACOLOGY OF CAFFEINE**

Caffeine is rapidly and completely absorbed from the GI tract, reaching a peak blood level within 30 to 45 minutes of oral ingestion. It easily crosses the blood–brain barrier, and levels achieved in the brain are proportional to the dose administered.

The half-life of caffeine in humans is approximately 3.5 to 5 hours. Serious problems rarely result from overdoses of caffeine. In fact, the amount of caffeine needed to cause death in an average adult male is 5 to 10 g, the equivalent of 50 to 100 cups of regular brewed coffee. Thus the risk of overdose from dietary sources of caffeine is virtually nonexistent.

Caffeine increases the heart rate and force of contraction. It also has a strong diuretic effect. The key factor promoting caffeine use and dosage increases can be the drug’s reinforcing effect on pleasure and reward centers of the brain. Caffeine’s pharmacologic actions appear comparable (although less potent) in some aspects with those of other stimulants, such as amphetamines and cocaine.

**CAFFEINE DEPENDENCE**

Research has shown that abstinence from caffeine induces a distinct withdrawal syndrome. Evidence for the existence of a caffeine dependence syndrome was presented by Strain and associates.38 In a structured psychiatric interview, subjects self-identified as having problems with caffeine use were evaluated for features of a DSM-IV-TR diagnosis of drug dependence. Those judged as caffeine dependent manifested at least three of four criteria (i.e., tolerance, withdrawal, persistent desire, or an unsuccessful attempt to reduce consumption and persistent use despite adverse psychologic or physical consequences). Of 99 people screened, 27 were evaluated by means of a structured psychiatric interview modified for the diagnosis of caffeine dependence; 16 of those subjects (59%) met the criteria. In a second phase of the study, 11 of the 16 caffeine-dependent individuals participated in a 2-day double-blind crossover study of caffeine deprivation. Nine showed evidence of caffeine withdrawal during the placebo phase, a finding that validated one of the criteria for the diagnosis of dependence.

**CAFFEINE WITHDRAWAL**

The frequency of the caffeine withdrawal syndrome is not well known, but it may be common. Withdrawal can occur when individuals who previously have been consuming caffeine on a regular basis suddenly discontinue its intake.39 The syndrome can be characterized by the occurrence of headache, drowsiness, fatigue, and sometimes impaired psychomotor performance, difficulty concentrating, nausea, excessive yawning, and craving. These symptoms usually appear within 18 to 24 hours of discontinuation of intake, corresponding to the time required for the drug to leave the body.

The caffeine withdrawal headache is somewhat unique, starting with a sense of fullness in the head and progressing to throbbing and diffuse pain that is made worse by movement. The maximum intensity of the pain occurs 3 to 6 hours after beginning.
When caffeine is reintroduced, relief of withdrawal symptoms tends to occur within 30 to 60 minutes. At present, this appears to be the most effective “treatment” for the caffeine-withdrawal syndrome.

EFFECT ON SLEEP

Caffeine interferes with sleep in most nontolerant individuals. Once tolerance has developed, people are much less likely to self-report sleep abnormalities, or they may sense that the insomnia has disappeared altogether. To illustrate, 53% of those consuming less than 250 mg/day agreed that caffeine before bedtime would prevent sleep, compared with 43% of those consuming 250 to 749 mg/day, and only 22% of those taking 750 mg/day or more. Even though the higher-level consumers denied that caffeine interferes with their sleep, studies done in the sleep laboratory confirm that caffeine consumers do have greater sleep latency, more frequent awakenings, and altered sleep architecture, and that these effects are dose related.

CAFFEINE DURING PREGNANCY

Over the years there has been much discussion on whether or not caffeine intake during pregnancy is harmful to the developing fetus. Results of research have been mixed, but in general, caffeine has not been shown to be a potent and consistent teratogen. Kuczkowski recently published a review article highlighting the implications of caffeine intake in pregnancy, reviewing the latest evidence-based information available on this subject, and offering recommendations for practitioners providing peripartum care to expectant mothers who consume caffeine.

Based on the data reviewed, the author concluded that for the healthy pregnant adult, moderate daily caffeine intake at a dose level up to 400 mg/day (equivalent to 6 mg/kg body weight per day in a 65-kg [143 lb] person) is not associated with adverse effects such as general toxicity, cardiovascular effects, effects on bone status and calcium balance, changes in adult behavior, increased incidence of cancer, or effects on fertility. The study did not identify any significant positive associations between maternal caffeine consumption and cardiovascular malformations.

The March of Dimes advises women to limit their caffeine intake to less than 200 mg per day. This recommendation was prompted by the results of a study published in March 2008 reporting that pregnant women who consumed 200 mg or more of caffeine a day had double the risk of miscarriage compared with those who had no caffeine. Criticism of this study was swift to follow, and its conclusions have been called into question.

CAFFEINE AND HEADACHES

A recent Norwegian study investigated the association between caffeine consumption and headache type and frequency in the general adult population. The results were based on cross-sectional data from 50,483 (55%) out of 92,566 invited participants aged greater than or equal to 20 years. A weak but significant association (OR, 1.16; 95% CI, 1.09–1.23) was found between high caffeine consumption and prevalence of infrequent headache. In contrast, headache greater than 14 days/month was less likely among individuals with high caffeine consumption compared to those with low caffeine consumption. The authors speculate that their results may indicate that high caffeine consumption changes chronic headache into infrequent headache due to the analgesic properties of caffeine. Alternatively, chronic headache sufferers tend to avoid intake of caffeine to not aggravate their headaches, whereas individuals with infrequent headache are less aware that high caffeine use can be a cause.

TREATMENT

Caffeinism

Caffeinism is treated by reducing or discontinuing the drug. It may be necessary to wean the patient off the drug gradually because going “cold turkey” can produce such serious symptoms that the drug must be restarted. Decaffeinated beverages can be substituted slowly for the caffeinated type. However, relapses are less likely to occur when the drug is discontinued all at once, probably because of the considerable self-discipline required to continue weaning the drug when one knows that an increase in dose will cause the symptoms to abate.

Patients with cardiovascular disease, especially arrhythmias, history of stroke or transient ischemic attacks should refrain totally. Patients with peptic ulcer disease, bipolar mood disorder, and schizophrenia should also be encouraged to avoid caffeine altogether.

The reader wishing more information about treatment of caffeine withdrawal should consult the systematic review by Juliano and Griffiths. A review of research on coffee and its health effects has also been published and should be consulted for in-depth discussion of this issue.

CONCLUSIONS

Use of alcohol, tobacco, and caffeine is so commonly accepted in our society that people take notice only when their use causes serious problems. When problems do occur, the human and economic costs are enormous. Healthcare professionals must be committed to helping people free themselves of the addictions that can occur with these common drugs.

The pathophysiology of schizophrenia may occur in one or more different neurotransmitter systems.

The clinical presentation of schizophrenia is characterized by positive symptoms, negative symptoms, and impairment in cognitive functioning.

Comprehensive care for individuals with schizophrenia must occur in the context of a multidisciplinary mental healthcare environment that offers psychotropic medication management and comprehensive psychosocial services.

A thorough patient evaluation (e.g., history, mental status exam, physical exam, psychiatric diagnostic interview, and laboratory analysis) should occur to establish a diagnosis of schizophrenia and to identify potential co-occurring disorders, including substance abuse and general medical disorders.

Given that it is challenging to differentiate among antipsychotics based upon efficacy, side-effect profiles become important in choosing an antipsychotic for an individual patient.

Pharmacotherapy algorithms should emphasize monotherapies with antipsychotics of optimal efficacy: side-effect ratios and progress to medications with greater side-effect risks and then to combination regimens only in the most treatment-resistant patients.

Adequate time on a given medication at a therapeutic dose is the most important variable in predicting medication response.

Long-term, maintenance antipsychotic treatment is necessary for the vast majority of patients with schizophrenia in order to prevent relapse.

Thorough patient and family psychoeducation should occur, including education about the illness, symptoms, prognosis, medication, psychosocial treatments, and methods to improve adaptive functioning.

Schizophrenia is one of the most complex and challenging of psychiatric disorders. It represents a heterogeneous syndrome of disorganized and bizarre thoughts, delusions, hallucinations, inappropriate affect, and impaired psychosocial functioning. From the time that Kraepelin first described dementia praecox in 1896 until publication of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) in 2000, the description of this illness has continuously evolved.

Scientific advances that increase our knowledge of central nervous system (CNS) physiology, pathophysiology, and genetics will likely improve our understanding of schizophrenia in the future.

Schizophrenia is one of the most complex and challenging of psychiatric disorders. It represents a heterogeneous syndrome of disorganized and bizarre thoughts, delusions, hallucinations, inappropriate affect, and impaired psychosocial functioning. From the time that Kraepelin first described dementia praecox in 1896 until publication of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) in 2000, the description of this illness has continuously evolved.

Scientific advances that increase our knowledge of central nervous system (CNS) physiology, pathophysiology, and genetics will likely improve our understanding of schizophrenia in the future.

According to the Epidemiologic Catchment Area Study, the lifetime prevalence of schizophrenia using strict diagnostic criteria ranges from 0.6% to 1.9%. If a broader definition is used, the lifetime rate rises to 2% to 3%. The worldwide prevalence of schizophrenia is remarkably similar among most cultures. Schizophrenia most commonly has its onset in late adolescence or early adulthood and rarely occurs before adolescence or after the age of 40 years. Although the prevalence of schizophrenia is equal in males and females, the onset of illness tends to be earlier in males. Males most frequently have their first episode during their early 20s, whereas with females it is usually during their late 20s to early 30s.

Although the etiology of schizophrenia is unknown, research has demonstrated various abnormalities in brain structure and function. However, these changes are not consistent among all individuals with schizophrenia. The cause of schizophrenia is likely multifactorial; that is, multiple pathophysiologic abnormalities can play a role in producing the similar but varying clinical phenotypes we refer to as schizophrenia.

A neurodevelopmental model has been evoked as one possible explanation for the etiology of schizophrenia. This model proposes that schizophrenia has its origins in some as yet unknown in utero disturbance, possibly occurring during the second trimester of pregnancy. Evidence for this is provided by the abnormal neuronal migration demonstrated in studies of schizophrenic brains. This “schizophrenic lesion” can result in abnormalities in cell shape, position, symmetry, connectivity, and functionally to the
development of abnormal brain circuits. Changes are consistent with a cell migration abnormality during the second trimester of pregnancy, and some studies associate upper respiratory infections during the second trimester of pregnancy with a higher incidence of schizophrenia. Other studies show a relationship between obstetric complications or neonatal hypoxia and schizophrenia. Some studies associate low birth weight (less than 2.5 kg [5.5 lb]) with schizophrenia. Maternal stress, perhaps related to the effects of circulating glucocorticoids in utero, may be a risk factor for schizophrenia. Maternal “stress” could derive from a variety of external and internal noxious events (malnutrition, infection, etc.). The resulting secondary “synaptic disorganization” associated with such insults is thought not to produce overt clinical manifestations of psychosis until adolescence or early adulthood because this is the corresponding time period of neuronal maturation.

Although studies have shown decreased cortical thickness and increased ventricular size in the brains of many patients with schizophrenia, this occurs in the absence of widespread gliosis. One hypothesis is that obstetric complications and hypoxia, in combination with a genetic predisposition, could activate a glutamatergic cascade that results in increased neuronal pruning. It is hypothesized that this genetic predisposition may be related to genes controlling N-methyl-D-aspartate (NMDA) receptor activity. As a part of the normal neurodevelopmental process, pruning of dendrites occurs. In normal individuals, approximately 35% of the peak number of dendrites at 2 years of age are pruned by midadolescence. Some studies have shown a higher percentage of pruning in individuals with schizophrenia. Furthermore, synaptic pruning predominantly involves glutamatergic dendrites. Hypoxia or other prenatal insult can result in a decreased number of basal neurons from which to start, and glutamatergic activation can exaggerate the pruning process.

Numerous studies have shown neuropsychologic abnormalities and impairment in reaching normal motor milestones and abnormal movements in young children who later develop schizophrenia. Abnormalities in brain function occur long before the onset of psychotic symptomatology and provide empiric evidence for schizophrenia being a neurodevelopmental disorder. However, the progressive clinical deterioration in many patients suggests that this illness can also have a neurodegenerative component. This is consistent with recent brain imaging studies that show deteriorative brain changes in patients with frequent relapses. Schizophrenia may be neither neurodevelopmental or neurodegenerative in origin, but rather an illness exhibiting neurodegenerative propensity based on a vulnerable neurodevelopmental predisposition.

**GENETICS**

Although a specific abnormality has not been discovered, evidence suggests a genetic basis for schizophrenia. Although the risk of developing schizophrenia is 0.6% to 1.9% in the U.S. population, the risk is approximately 10% if a first-degree relative has the illness and 3% if a second-degree relative has the illness. If both parents have schizophrenia, the risk of producing a schizophrenic offspring increases to approximately 40%. Twin studies in dizygotic twins report that the risk of the second twin developing schizophrenia if one twin has the illness is between 12% and 14%. However, in monozygotic twins the risk increases to 48%. Numerous adoption studies indicate that the risk for schizophrenia lies with the biologic parents, and change in the environment during the child’s developmental stages does not alter this. If schizophrenia occurs in siblings, the onset of illness tends to occur at the same age in each, thus lessening the possibility of an environmental precipitant. A search for a genetic linkage in schizophrenia has been difficult, and any genetic etiologies in schizophrenia are likely heterogeneous, but present with similar phenotypes. Potential loci have been identified on chromosomes 6, 8, 13, and 22. The study of the genetics of schizophrenia has become increasingly molecular in focus. Recent work has shown that polymorphism in the VAL/MET alleles of the catecholamine-O-methyl transferase gene can explain some of the frontal lobe functional deficits in a subset of individuals with schizophrenia. Other recent studies have shown abnormalities in several genes that code for neurodevelopment and for trophic factors. For example, dysbindin is a neurodevelopmental protein gene that is found on chromosome 6. Alleles associated with decreased dysbindin RNA in the dorsolateral prefrontal cortex have been reported in patients with schizophrenia and their families. Another recent gene-wide linkage scan of a large pedigree showed increased signal at chromosome 8p, close to the gene that encodes for neuregulin—a neurodevelopmental gene. Of particular excitement in the field has been the discovery of an overexpression of copy number variants (CNVs) in schizophrenia. This work has fueled other new large-scale genetic studies that are ongoing in an attempt to replicate these findings.

**PATHOPHYSIOLOGY**

Computed axial tomography (CAT) scans and magnetic resonance imaging (MRI) studies show increased ventricular size, particularly in the third and lateral ventricles, in subtypes of schizophrenics. Recent studies also show a small decrease in brain size compared to matched controls. These changes appear to be consistent with brain asymmetry, the ventricular enlargement being most pronounced in the left temporal horn, and the decreased cortical size being most obvious in the left temporal lobe. Not only does premorbid lower hippocampal volume predict onset of symptoms in high-risk individuals, these structural changes can progress throughout the course of the illness. A reduction in medial temporal lobe volume has been reported in high-risk patients after they were scanned, indicating that some brain changes can be associated with the evolution of psychosis. In an extended analysis, high-risk subjects were compared with first-episode chronic schizophrenia and normal control groups according to hippocampal and amygdala volumes at baseline. No difference in MRI volumes between the high-risk subjects and normal controls were observed, irrespective of whether the at-risk patients did or did not progress to overt psychosis. First-episode schizophrenia (but not other psychosis) groups had reduced (left) hippocampal volume. The implication that these changes occur during transition is intriguing and accords well with the notion of psychosis as a biologically toxic event. Changes in hippocampal volume may correspond with impairment in neuropsychologic testing. Rather than a decrease in the number of neurons in affected brain areas, a decrease in axonal and dendritic communications between cells can result in a loss of connectivity that can be important with respect to neuronal adaptivity and CNS homeostasis. These changes are likely consistent with the evidence for abnormal neuronal pruning.

**NEUROTRANSMITTER CHANGES**

Four dopaminergic tracts are of primary interest. Table 76–1 outlines the origin, innervation, and primary functional activity of each tract, as well as the effects of dopamine (DA) antagonists. Evidence supports the presence of a DA-receptor defect in schizophrenia. Numerous positron emission tomography (PET) studies have shown regional brain abnormalities, including increased glucose metabolism in the caudate nucleus and decreased blood flow and glucose metabolism in the frontal lobe and left temporal lobe. This can indicate dopaminergic hyperactivity in the head of the
caeruleus nucleus and dopaminergic hypofunction in the frontotemporal regions. PET studies using dopamine-2 (D2)–specific ligands suggest increased densities of D2 receptors in the head of the caudate nucleus with decreased densities in the prefrontal cortex.3,4 PET studies assessing dopamine-1 (D1) function suggest that subpopulations of schizophrenics may have decreased densities of D1 receptors in the caudate nucleus and the prefrontal cortex. Hypofrontality can be associated with lack of volition and cognitive dysfunction, core features of schizophrenia. It is unknown whether these changes represent a primary event or secondary processes related to other pathophysiologic abnormalities in schizophrenia. Because of the heterogeneity in the clinical presentation of schizophrenia, it has been suggested that the DA hypothesis can be more applicable to “neuroleptic-responsive psychosis,” with multiple different etiologies possibly being responsible for causing schizophrenia.2 Attempts have been made to develop relationships between these abnormal findings and behavioral symptoms present in schizophrenic patients. The positive symptoms are possibly more closely associated with DA-receptor hyperactivity in the mesocaudate, whereas negative symptoms and cognitive impairment are most closely related to DA-receptor hypofunction in the prefrontal cortex. Presynaptic D2 receptors in the prefrontal cortex are thought to be involved in modulating glutamatergic activity, and this can be important with regard to working memory in individuals with schizophrenia.2

The glutamatergic system is one of the most widespread excitatory neurotransmitter systems in the brain. Alterations in its function, either hypo- or hyperactivity, can result in toxic neuronal reactions.3 Dopaminergic innervation from the ventral striatum decreases the limbic system’s inhibitory activity (perhaps through γ-aminobutyric acid [GABA] interneurons); thus, dopaminergic stimulation increases arousal. The corticostriatal glutamate pathways have the opposite effect, inhibiting dopaminergic function from the ventral striatum, therefore allowing the limbic system to have increased inhibitory activity. Descending glutamatergic tracts interact with dopaminergic tracts directly as well as through GABA interneurons. Glutamatergic deficiency produces symptoms similar to those of dopaminergic hyperactivity and possibly those seen in schizophrenia. Clinical support for this comes from the fact that phencyclidine, a potent psychotomimetic, is a noncompetitive antagonist at the NMDA receptor, a major glutamate receptor. Similarly, abuse of ketamine, a veterinary anesthetic, can resemble schizophrenia. Ketamine, a competitive antagonist at glutamatergic NMDA receptors, has been shown to lead to reduction in D2 neurotransmission through glutamatergic inhibition of DA release.17 It is proposed that schizophrenia may involve some in utero assault that leads to a developmental defect in NMDA receptor function—so-called NMDA hypofunction. This defect is proposed to have latent clinical expression with the psychotic manifestations from NMDA hypofunction not being seen until late adolescence or early adulthood. It has been shown that excess D2 stimulation can impair NMDA transmission via GABAergic neurons. Thus the use of antipsychotic drugs may indirectly enhance glutamatergic transmission.2

Serotoninergic receptors are present on dopaminergic axons, and stimulation of these receptors decreases DA release, at least in the striatum.4 Although somewhat more diffuse, the distribution of serotoninergic neurons is similar to that of dopaminergic neurons, thus allowing these two neurotransmitter systems to innervate the same areas. In fact, 5-hydroxytryptamine, (serotonin-2; 5-HT2) receptors and D2 receptors have been found to be colocalized in the cortex.25 Patients with schizophrenia with abnormal brain scans have higher whole-blood 5-HT concentrations, and these concentrations are correlated with increased ventricular size.18 Second-generation antipsychotics (SGA), also known as atypical antipsychotics, with potent 5-HT2 receptor antagonist effects reverse worsening of symptomatology induced by 5-HT agonists in patients with schizophrenia.18

# Schizophrenia

Schizophrenia is a complex disorder, and multiple etiologies likely exist. Based on current knowledge, it is naive to think that any currently proposed etiology can adequately explain the genesis of this complex disease. Molecular research involving genetically determined subtle changes in G proteins, protein metabolism, and other subcellular processes can eventually identify the biologic disturbances associated with schizophrenia.24,8

## Clincial Presentation

Schizophrenia is the most common functional psychosis, and great variability occurs in clinical presentation. Despite numerous attempts to portray a stereotype in movies and on television, the stereotypic schizophrenic essentially does not exist. Moreover, schizophrenia is not a “split personality.” It is a chronic disorder of thought and affect with the individual having a significant disturbance in interpersonal relationships and ability to function in society.

The first psychotic episode can be sudden in onset with few premorbid symptoms, or commonly can be preceded by withdrawn, suspicious, peculiar behavior (schizoid). During acute psychotic episodes, the patient loses touch with reality, and in a sense, the brain creates a false reality to replace it. Acute psychotic symptoms can include hallucinations (especially hearing voices), delusions (fixed false beliefs), and ideas of influence (beliefs that one’s actions are controlled by external influences). Thought processes are disconnected (loose associations), the patient may not be able to carry on logical conversation (alogia), and can have simultaneous contradictory thoughts (ambivalence). The patient’s affect can be flat (no emotional expression), or it can be inappropriate and labile. The patient is often withdrawn and inwardly directed (autism). Uncooperativeness, hostility, and verbal or physical aggression can be seen because of the patient’s misperception of reality. Self-care skills are impaired, and the patient is frequently dirty, unkempt, and in general has poor hygiene. Sleep and appetite are often disturbed. When the acute psychotic episode remits, the patient typically has residual features. This is an important point in differentiating schizophrenia from other psychotic disorders. Although residual

symptoms and their severity vary, patients can have difficulty with anxiety management, suspiciousness, and lack of volition, motivation, insight, and judgment. Therefore, they often have difficulty living independently in the community. Because of poor anxiety management and suspiciousness, they are frequently withdrawn socially, and have difficulty forming close relationships with others. In addition, impaired volition and motivation contribute to poor self-care skills and make it difficult for the patient with schizophrenia to maintain employment.

Patients with schizophrenia frequently experience a lack of historicity, or difficulty in learning from their experiences. They can repeatedly make the same mistakes in social conduct and situations requiring judgment. They have difficulty understanding the importance of treatment, including medications, in maintaining their ability to function in society. Therefore, they tend to discontinue medications and other treatments, and this increases the risk of relapse and rehospitalization. The co-occurrence of substance abuse (predominantly alcohol or polysubstance—alcohol, cannabis, cocaine) in patients with schizophrenia is very common and is another frequent reason for relapse and hospitalization.\(^\text{18}\) This effect can be caused by direct toxic effects of these drugs on the brain,\(^\text{19}\) but is also caused by the medication nonadherence that is associated with substance abuse.

Although the course of schizophrenia is variable, the long-term prognosis for many patients is poor. It is marked by intermittent acute psychotic episodes and impaired psychosocial functioning between acute episodes, with most of the deterioration in psychosocial functioning occurring within 5 years after the first psychotic episode.\(^\text{20}\) By late life, the patient can appear “burned out,” that is, the patient ceases to have acute psychotic episodes, but residual symptoms persist. In a subgroup of patients, probably 5% to 15%, psychotic symptoms are nearly continuous, and response to antipsychotics is poor.\(^\text{19}\)

Schizophrenia is a chronic disorder, and the patient’s history must be carefully assessed for dysfunction that has persisted for longer than 6 months. After their first episode, patients with schizophrenia rarely have a level of adaptive functioning as high as before the onset of the disorder. Table 76–2 summarizes the DSM-IV-TR criteria.\(^\text{1}\)

### Table 76-2 DSM-IV-TR Diagnostic Criteria for Schizophrenia

<table>
<thead>
<tr>
<th>A. Characteristic symptoms: Two or more of the following, each persisting for a significant portion of at least 1-month period:</th>
</tr>
</thead>
<tbody>

<tr>
<td>(5) Negative symptoms</td>
</tr>
</tbody>
</table>

**Note:** Only one criterion A symptom is required if delusions are bizarre or if hallucinations consist of a voice keeping a running commentary on the person’s behavior or two or more voices conversing with each other.

| B. Social/occupational dysfunction: For a significant portion of the time since onset of the disorder, one or more major areas of functioning such as work, interpersonal relations, or self-care are significantly below the level prior to onset. |

| C. Duration: Continuous signs of the disorder for at least 6 months. This must include at least 1 month of symptoms fulfilling criterion A (unless successfully treated). This 6 months may include prodromal or residual symptoms. |

| D. Schizoaffective or mood disorder has been excluded. |

| E. Disorder is not due to a medical disorder or substance use. |

| F. If a history of a pervasive developmental disorder is present, there must be symptoms of hallucinations or delusions present for at least 1 month. |

2. The DSM-IV-TR classifies the symptoms of schizophrenia into two categories: positive and negative. Recently greater emphasis has been placed on a third symptom category, cognitive dysfunction (Table 76–3).\(^\text{19}\) The areas of cognition found to be abnormal in schizophrenia include attention, working memory, and executive function. Positive symptoms have traditionally attracted the most attention and are the ones most improved by antipsychotics. However, negative symptoms and impairment in cognition are more closely associated with poor psychosocial function. Along with these characteristic features of schizophrenia, many patients also have comorbid psychiatric and general medical disorders.\(^\text{19,20}\) These include depression, anxiety disorders, substance abuse, and general medical disorders like respiratory disorders and metabolic disturbances. These comorbidities substantially complicate the clinical presentation and course of schizophrenia.

It has been suggested that symptom complexes can correlate with prognosis, cognitive functioning, structural abnormalities in the brain, and response to antipsychotic drugs. Negative symptoms and cognitive impairment can be more closely associated with prefrontal lobe dysfunction and positive symptoms with temporo-limbic abnormalities. Many patients demonstrate both positive and negative symptoms. Patients with negative symptoms frequently have more antecedent cognitive dysfunction, poor premorbid adjustment, low level of educational achievement, and a poorer overall prognosis.\(^\text{19}\)

### TREATMENT

#### NONPHARMACOLOGIC THERAPY

Psychosocial rehabilitation programs oriented toward improving patients’ adaptive functioning are the mainstay of nondrug treatment for schizophrenia. These programs can include case management, psychoeducation, targeted cognitive therapy, basic living skills, social skills training, basic education, work programs, supported housing, and financial support. In particular, programs aimed at employment and housing have been the more effective...
interventions and are considered “best practices.” Programs that involve families in the care and life of the patient have been shown to decrease rehospitalization and improve functioning in the community. For particularly low-functioning patients, assertive intervention programs, referred to as active community treatment (ACT), are effective in improving patients’ functional outcomes. ACT teams are available on a 24-hour basis and work in the patient’s home and place of employment to provide comprehensive treatment, including medication, crisis intervention, daily living skills, and supported employment and housing.\textsuperscript{19,20} Medication treatment cannot be successful without proper attention to these other aspects of care. People with schizophrenia need comprehensive care, with coordination of services across psychiatric, addiction, medical, social, and rehabilitative services. The level of coordination in the United States is often insufficient, and patients become at risk to “fall through the cracks.” Recent national policy documents have called for greater coordination of care.\textsuperscript{21,22} Additionally, emphasis is growing on the role that the person himself or herself plays in a recovery-based system of care, where the person’s lifetime aspirations and goals become the center of care, rather than symptom reduction being the primary focus. This recovery-based approach recognizes the strengths and resilience of people with schizophrenia.\textsuperscript{23} It also acknowledges how people with schizophrenia can also be a support to others who are coping with the illness.\textsuperscript{24} It is important to frame clinical decision making in the context of a mutual process involving patient and clinician—rather than a unilateral “here’s a prescription…please take these tablets” approach. Also, it is increasingly recognized that cognitive behavioral therapy can help some patients. A list of psychotherapeutic approaches to the treatment of schizophrenia is given in Table 76–4.

**PHARMACOTHERAPEUTIC ALGORITHM**

Figure 76–1 outlines a suggested pharmacotherapeutic algorithm for schizophrenia.\textsuperscript{23,26,28} Stage 1 of the treatment algorithm applies to those patients experiencing their first episode of schizophrenia or to patients off of medications and re-entering treatment who do not have a history of nonresponse or nontolerance with antipsychotics. The clinician needs to evaluate the relative risk of extrapyramidal side effects (EPS) with FGAs versus the risk of metabolic side effects with different SGAs in making a decision for drug selection. The 2009 PORT recommendations do not recommend the use of olanzapine in first episode because of weight gain and metabolic side effects.\textsuperscript{29} Stage 2 addresses pharmacotherapy in a patient who had inadequate clinical improvement with the antipsychotic used in stage 1. Stage 2 recommends an alternate antipsychotic monotherapy with the exception of clozapine.\textsuperscript{23,26}

Because of safety concerns and the need for white blood cell (WBC) monitoring, it is recommended that patients be tried on different monotherapy antipsychotic trials before proceeding to a trial of clozapine (stage 3).\textsuperscript{24,28} Clozapine has superior efficacy in decreasing suicidal behavior, and it should be considered as a higher treatment option in the suicidal patient.\textsuperscript{23,26} Clozapine can also be considered earlier in treatment in patients with a history of violence or comorbid substance abuse.\textsuperscript{23,26}

Stage 4 of the treatment algorithm includes clozapine and augmentation with either a FGA, SGA, or electroconvulsive therapy (ECT).\textsuperscript{25} Treatment algorithm recommendations after stage 3...
Algorithm for the pharmacotherapy of schizophrenia

Choice of antipsychotic (AP) should be guided by considering the clinical characteristics of the patient and the efficacy and side effect profiles of available medication.

Forward stage(s) can be skipped depending on clinical picture or history of antipsychotic failures, and returning to an earlier stage may be justified by history of past response.

**Stage 1**

* First episode patients usually require lower antipsychotic dosing and should be closely monitored due to greater sensitivity to medication side effects.

**Stage 2**

Trial of a single SGA or FGA

Partial or no response

**Stage 3**

Clozapine monotherapy

Partial or no response

**Stage 4**

Clozapine (FGA, SGA or ECT)

No response

**Stage 5**

Trial of a single agent FGA or SGA (not tried in stages 1 or 2)

No response

**Stage 6**

Combination therapy e.g., SGA + FGA, combination of SGAs, (FGA or SGA) + ECT, (FGA or SGA) + other agent (e.g., mood stabilizer)

Consider earlier trial of clozapine in patients with a history of recurrent suicidality, violence, or comorbid substance abuse. Persistence of positive symptoms > 2 years warrants or poor functioning > 5 years requires a clozapine trial, independent of number of preceding antipsychotic trials.

* First episode patients usually require lower antipsychotic dosing and should be closely monitored due to greater sensitivity to medication side effects.

**A** treatment refractory evaluation should be performed to reexamine diagnosis, substance abuse, medication adherence, and psychosocial stressors. Cognitive behavioral therapy and other psychosocial augmentations should be considered.

Whenever a second medication is added to an antipsychotic (other than clozapine) for the purpose of improving psychotic symptoms, the patient is considered to be in stage 6.

**FIGURE 76-1.** Patient entry into the algorithm is determined by individual patient history, clinical presentation, and consideration of potential side-effect risk. Either first episode patients or patients who have been off of medications and are reentering treatment with no history of poor response to antipsychotics are entered at stage 1. Algorithm stages can be skipped if clinically appropriate, and one can go back stages if indicated. In general, inadequately responding patients should not remain in stages 1 or 2 longer than 12 weeks at therapeutic doses. Stage 3 should be at least 6 months. In stages 4, 5, and 6, a 12-week trial is recommended, and if there is greater than or equal to 20% improvement in positive symptoms at week 12, the medication trial warrants extension for an additional 12 weeks with dose titration as clinically warranted. The levels of evidence for algorithm recommendations are as follows: stage 1, level A for efficacy for both first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs); stage 2, level A; stage 3, level A; stage 4, level C; stage 5, level C; stage 6, level C. Level A is supported by one or more randomized controlled trials. Level B is supported by large cohort studies, epidemiologic studies, and so on. Level C is supported only by case series, case reports, or expert opinion. (Created based upon references 25, 26, 28.)
(i.e., clozapine monotherapy) are based more on anecdotal experiences and expert opinion than on empirical research. In general, patients who experience poor improvement with clozapine do not respond well with other antipsychotic monotherapies (stage 5), thus the primary reason that clozapine augmentation is recommended at stage 4. Stage 6 combination pharmacotherapy interventions are not evidence based and should only be implemented with time limited, careful evaluation of a patient’s symptom response and discontinuation of the combination if improvement does not occur.

If partial or poor adherence contributes to inadequate clinical improvement, then long-acting injectable antipsychotics should be considered. In addition to individuals who are identified as partially adherent, some patients may elect for long-acting injections instead of taking daily oral medication. A long-acting injectable antipsychotic can be substituted for an oral antipsychotic at any point in the algorithm where it is thought to be indicated.

The use of antipsychotic combinations is controversial, as limited evidence supports increased efficacy for combination antipsychotic treatment.

**CLINICAL CONTROVERSY**

Significant controversy exists regarding whether to use an FGA or an SGA as first-line treatment in schizophrenia. Although some studies have demonstrated a lower incidence of EPS with SGAs, weight gain and the risk of diabetes mellitus are significant adverse events with some of the SGAs, particularly olanzapine. Tension also exists between policy decision makers who are responsible for managing finite resources and clinicians who see clinical benefits of the SGAs in the patients they treat. The use of antipsychotic combinations is controversial, as insufficient evidence exists to support their use. Regardless, combination antipsychotics are frequently used by clinicians, and testimonies attest to clinical benefits when a second SGA is added.

### PREDICTORS OF RESPONSE

Obtaining a thorough medication history is important, and previous antipsychotic treatment should help guide the selection of drug therapy, in that either a good prior response favors the use of the same agent or a negative prior response suggests the selection of a dissimilar drug. Nonprescription and illicit drug use can influence psychiatric presentation and thus diagnosis or antipsychotic response. Amphetamines and other CNS stimulants, cocaine, corticosteroids, digoxis glycosides, indomethacin, marijuana, pentazocine, phenycyclidine, and other drugs can induce psychosis in susceptible individuals or exacerbate psychosis in patients with preexisting psychiatric illness. Patients with schizophrenia who continue to abuse alcohol or drugs usually have a poor response to medications and a poor prognosis. Alcohol, caffeine, and nicotine use potentially results in drug interactions.

Individual differences in patient response have been either proposed or identified, which can be clinically useful predictors of response. Acute onset and short duration of illness, presence of acute stressors or precipitating factors, later age of onset, family history of affective illness, and good premorbid adjustment as reflected in stable interpersonal relationships or employment are all predictors of good response.

Although controversial, affective symptoms can correlate with an overall good response. Negative symptoms and neuropsychologic deficits related to cognition and neurologic soft signs can correlate with poor antipsychotic response. A patient’s subjective response within the first 48 hours after being administered an FGA can be associated with drug responsiveness. An initial dysphoric response, demonstrated by stating a dislike of the medication, or feeling worse or zombie-like, combined with anxiety or akathisia-like symptoms, is associated with poor drug response, adverse effects, and nonadherence.

The importance of developing a therapeutic alliance between the patient and the clinician cannot be underestimated. Patients who

form positive therapeutic alliances are more likely to be adherent with all aspects of therapy, experience a better outcome at 2 years, and require smaller antipsychotic doses.

A certain minority of patients fail to benefit from antipsychotic therapy, and their psychosocial functioning can actually worsen. Unfortunately, no accepted method is available to identify these people before treatment. Recent evidence suggests that pharmacogenetics can play a role in predicting treatment response, both with respect to symptom improvement and with liability to develop side effects. However, insufficient information is available to recommend routine clinical testing.

## INITIAL TREATMENT IN AN ACUTE PSYCHOTIC EPISODE

The goals during the first 7 days of treatment should be decreased agitation, hostility, combativeness, anxiety, tension, and aggression, and normalization of sleep and eating patterns. The usual recommendation is to initiate therapy and to titrate dose over the first few days to an average effective dose, unless the patient’s physiologic status or history indicates that this dose can result in unacceptable adverse effects. Table 76–5 lists the usual dosage range, and an average dose is typically midrange. Because of increased sensitivity to side effects, particularly extrapyramidal side effects, in first-episode psychotic patients, typical dosing ranges are approximately 50% of the doses used in chronically ill individuals. If “cheeking” of medication is suspected, liquid formulations and orally disintegrating tablets of different antipsychotics are available (see Table 76–5). If a patient has shown absolutely no improvement after 3 to 4 weeks at therapeutic doses, then an alternative antipsychotic should be considered (i.e., moving to the next treatment stage in the algorithm; see Fig. 76–1).

Although some clinicians believe that larger daily doses are necessary in more severely symptomatic patients, data are not available to support this practice. Some symptoms, such as agitation, tension, aggression, and increased motor activity, can respond more quickly, but side effects can be more common with higher doses. However, interindividual differences in dosage and patient response do occur. In partial but inadequate responders who are tolerating the chosen antipsychotic, it may be reasonable to titrate above usual dose ranges. However, this tactic should be time-limited (i.e., 2–4 weeks), and if the patient does not achieve further improvement, the dose should either be decreased, or an alternative treatment strategy tried. In general, rapid titration of antipsychotic dosage is not indicated. However, intramuscular antipsychotic administration (e.g., aripiprazole 5.25–9.75 mg IM, haloperidol 2–5 mg IM, olanzapine 2.5–10 mg IM, or ziprasidone 10–20 mg IM) can be used to assist in calming a severely agitated patient. Agitation can be manifested as loud, physically or verbally threatening behavior, motor hyperactivity, or physical aggression. Although this technique can assist in calming an acutely agitated psychotic patient, it does not improve the extent of or time to remission, or the length of hospitalization. If haloperidol IM is used, the occurrence of EPS can eliminate some of the advantages of using an oral SGA. If the patient is receiving an antipsychotic within the usual therapeutic range, the use of lorazepam 2 mg IM as needed in combination with the maintenance antipsychotic is a rational alternative to an injectable antipsychotic. Hypotension, respiratory depression, and CNS depression are possible when injectable lorazepam and olanzapine are used concomitantly; thus this parenteral combination is not recommended.

## STABILIZATION THERAPY

Minimal research evidence supports the use of antipsychotic doses beyond the dose range in the FDA-approved product labeling. However, clinicians frequently titrate doses above the approved range, and frequently attest to symptom improvement when this is done.

Improvement is usually a slow but steady process over 6 to 12 weeks or longer. During the first 2 to 3 weeks, goals should include increased socialization and improvement in self-care habits and mood. Improvement in formal thought disorder should follow and can take an additional 6 to 8 weeks to respond. Patients who are early in the course of their illness can experience a more rapid resolution of symptoms than individuals who are more chronically ill. In general, if a patient has no improvement with treatment after 3 to 4 weeks at therapeutic doses, or has achieved only a partial decrease in positive and negative symptoms within 12 weeks at adequate doses, then the next algorithm stage should be considered. In more chronically ill patients, symptoms can continue to improve for 3 to 6 months. During acute stabilization, usual labeled doses of SGAs are recommended (see Table 76–5); with FGAs, a range of 300 to 1,000 mg of chlorpromazine equivalents daily is recommended. An optimum dose of the chosen drug should be estimated in the initial treatment plan. If the patient begins to show adequate response before or at this dosage, then the patient should remain at this dosage as long as symptoms continue to improve.

In general, adequate time on a therapeutic antipsychotic dose is the most important factor in predicting medication response. However, if necessary, dose titration can continue within the therapeutic range every week or two as long as the patient has no side effects.

Before changing medications in a poorly responding patient, the following should be considered: Were the initial target symptoms indicative of schizophrenia or did they represent manifestations of a different diagnosis, a long-standing behavioral problem, a substance abuse disorder, or a general medical condition? Is the patient adherent with pharmacotherapy? Are the persistent symptoms poorly responsive to antipsychotics (e.g., impaired insight or judgment, or fixed delusions)? How does the patient’s current status compare with response during previous exacerbations? Would this patient potentially benefit from a change to a different treatment stage (see Fig. 76–1)? Does this patient have a treatment-refractory schizophrenic illness?

The conclusion that a partially responding patient has achieved as much symptomatic improvement as possible is one that must be made with great care and after considering all possible treatment alternatives. However, treatment goals must be realistic. Medications are effective at decreasing many of the symptoms of schizophrenia (and are thus referred to as palliative), but they are not curative, and all symptoms may not abate. Although one should aim to achieve none to minimal residual positive symptoms with effective treatment, it is still unclear what a realistic goal is with regard to maximum improvement in negative symptoms.

It is important to screen patients for co-occurring mental disorders, and their presence can become more apparent during the stabilization or maintenance phases of schizophrenia treatment. Examples include substance abuse disorders, depression, obsessive-compulsive disorder, and panic disorder. As co-occurring disorders will limit symptom and functional improvement and increase the risk of relapse, it is critical that pharmacologic and nonpharmacologic
interventions for the co-occurring disorder be implemented in combination with evidence-based treatment for schizophrenia.

## MAINTENANCE TREATMENT

Maintenance drug therapy prevents relapse, as shown in numerous double-blind studies. The average relapse rate after 1 year is 18% to 32% with active drug (including some nonadherent patients) versus 60% to 80% for placebo.19,32

After treatment of the first psychotic episode in a schizophrenic patient, medication should be continued for at least 12 months after remission.19,32 Many schizophrenia experts recommend that patients with robust medication response be treated for at least 5 years. In chronically ill individuals, continuous or lifetime pharmacotherapy is necessary in the majority of patients to prevent relapse. This should be approached with the lowest effective dose of the antipsychotic that is likely to be tolerated by the patient.19,32

Antipsychotics should be tapered slowly before discontinuation. Abrupt discontinuation of antipsychotics, especially low-potency FGAs and clozapine, can result in withdrawal symptoms, felt to be a manifestation of rebound cholinergic outflow. Insomnia, nightmares, headaches, gastrointestinal symptoms (e.g., abdominal cramps, stomach pain, nausea, vomiting, and diarrhea), restlessness, increased salivation, and sweating are reported. When switching from one antipsychotic to another, it is often recommended to taper and discontinue the first antipsychotic over at least 1 to 2 weeks after the second antipsychotic is initiated.19,32 Tapering may need to occur more slowly, especially with clozapine.19,32

### Long-Acting Injectable Antipsychotics

Long-acting antipsychotics are recommended for patients who are unreliable in taking oral medication on a daily basis, and thus are not usually used as first-line therapy. Before a long-acting antipsychotic is initiated, it should be determined whether the patient’s medication nonadherence is because of side effects. If so, an alternative medication with a more favorable side-effect profile should be considered before a long-acting injectable antipsychotic.

The patient’s motivation for treatment is a major factor influencing outcome. Conversion from oral therapy to a long-acting injectable is most successful in patients who have been stabilized on oral therapy. The ideal patient for a long-acting injectable is the individual who does not like the daily reminder of oral medication or is unreliable in taking medications. Paliperidone palmitate is a long-acting injectable that has the advantage of once-monthly injections and easy conversion from oral to IM treatment. It has the disadvantage of being extremely expensive.14 A long-acting formulation of olanzapine is under FDA review at the time of publication.

Conversion from an oral antipsychotic to a long-acting medication should start with stabilization on an oral dosage form of the same agent, for a short trial (3–7 days), to determine whether the patient tolerates the medication without significant side effects. With long-acting risperidone, measurable serum concentrations are not seen until approximately 3 weeks after single-dose administration. Thus, it is important that the oral antipsychotic be administered for at least 3 weeks after beginning the injections. Dose adjustments are recommended to be made no more often than once every 4 weeks.22,23 The recommended starting dose with risperidone long-acting injection is 25 mg, and clinical experience suggests that titration to doses greater than or equal to 37.5 mg per injection may be necessary for maintenance treatment. Long-acting risperidone has demonstrated efficacy, with an optimum dose range between 25 and 50 mg given IM every 2 weeks. Doses above 50 mg every 2 weeks are not recommended, as research indicates no greater efficacy but more EPS.25,35

Paliperidone palmitate can be injected into either the deltoid or the gluteal muscle, and treatment is initiated with 234 mg on day 1 and 156 mg a week later. No overlap with oral drug is necessary. Monthly IM doses are then titrated according to response within a range of 39 to 234 mg.34

For fluphenazine decanoate, the simplest dosing conversion method recommends 1.2 times the oral fluphenazine daily dose for stabilized patients, rounding up to the nearest 12.5-mg interval, administered in weekly doses for the first 4 to 6 weeks; or 1.6 times the oral daily dose for more acutely ill patients.36 Subsequently, fluphenazine decanoate can be administered once every 2 to 3 weeks. Oral fluphenazine can be overlapped for 1 week. For haloperidol decanoate, a factor of 10 to 15 times the oral haloperidol daily dose is commonly recommended, rounding up to the nearest 50-mg interval, administered in a once-monthly dose with an oral haloperidol overlap for the first month. A more assertive conversion method recommends 20 times the oral daily dose, but dividing the injection into consecutive doses of 100 to 200 mg every 3 to 7 days until the entire amount is given.37 With this method, oral medication overlap is unnecessary. The haloperidol decanoate dose is decreased by 25% at both second and third month.

Injection site reactions have been reported with the haloperidol decanoate 100 mg/ml preparation, consisting of painful pruritic swelling at the injection site.38 Acute EPS can be seen following injections of either fluphenazine or haloperidol decanoate. These effects are minimized with the use of risperidone microspheres. Both haloperidol and fluphenazine decanoate should be administered by a deep, “Z-tract” intramuscular method. Long-acting risperidone is injected by deep IM injection in the gluteus maximus, but Z-tracting is not necessary.

### Methods to Enhance Patient Adherence

It is often a challenge for individuals with chronic illnesses to maintain high levels of medication adherence, and partial compliance is a reality in the treatment of all chronic illnesses.40 Individuals with serious mental disorders have somewhat higher nonadherence rates than those with general medical disorders, with the following explanations provided: denial of illness, lack of insight, grandiosity or paranoia, no perceived need for medication, perceived lack of input into choice of medication or dosage, side effects, misperceived “allergies,” or the number of medications prescribed or doses received daily. In fact, clinicians should expect partial compliance to be the norm with regard to medication-taking behavior. This should be approached in a nonjudgmental manner, with the clinician actively engaging the patient in care and using motivational interviewing techniques as mechanisms to enhance therapeutic alliance and patient adherence.

Education geared toward patients becoming more informed about their illness and the effectiveness and risks of treatment can help to increase adherence.41 These programs should be staged so that patients initially receive basic information about their disorder and its symptoms and basic information about their medication and self-monitoring techniques. As the patient is capable of dealing with more complex information, more detailed information regarding schizophrenia, psychosocial treatments, and prognosis should be discussed. Patients and families should be taught self-monitoring techniques and when to report symptom exacerbation or medication side effects to the clinician.42 Psychoeducation strategies should include motivational interview techniques in individual counseling as well as group activities.
Recent evidence suggests that cognitive behavioral therapy focusing on medication adherence can improve patient outcome. This approach is called compliance therapy. Groups facilitated by trained individuals who have the illness can be more effective in enhancing awareness and acceptance of schizophrenia and necessary treatment than groups led only by professionals. Active involvement of family members further increases the likelihood of patient adherence with treatment. In addition to programs provided by community mental health centers, support groups operated by consumer groups such as the National Alliance on Mental Illness (NAMI) are available in most urban areas. Contact information for local NAMI chapters can be accessed at www.nami.org. In the hospital, self-medication administration can reinforce the patient’s perception of their active role in their own treatment. When patients miss outpatient appointments, active outreach interventions must be implemented to enhance patient engagement in treatment.

Management of Treatment-Resistant Schizophrenia

In general, “treatment resistant” describes a patient who has had inadequate symptom response from multiple antipsychotic trials. Traditionally, treatment resistance has been defined as lack of improvement in positive symptoms, but it can be defined by poor improvement in negative symptoms, or even by medication intolerance. Between 10% and 30% of patients receive minimal symptomatic improvement after multiple FGA monotherapy trials. An additional 30% to 60% of patients have partial but inadequate improvement in symptoms or unacceptable side effects associated with antipsychotic use. In those patients failing two or more pharmacotherapy trials, a treatment refractory evaluation should be performed to reexamine diagnosis, substance abuse, medication adherence, and psychosocial stressors. Targeted cognitive behavioral therapy or other psychosocial augmentation strategies should be considered.

Clozapine

Only clozapine has shown superiority over other antipsychotics in randomized clinical trials for the management of treatment-resistant schizophrenia. Most other SGAs have either not been studied in treatment-refractory patients or evaluated in small open trials. In a seminal study, clozapine was effective in approximately 30% of patients with treatment-resistant schizophrenia, compared with only 4% treated with a combination of chlorpromazine and benztropine. The criteria for treatment-resistance require two treatment failures, and includes both FGAs and SGAs. Other treatment candidates for clozapine include those patients who cannot tolerate even conservative doses of other antipsychotics.

Symptomatic improvement with clozapine in the treatment-resistant patient often occurs slowly, and as many as 60% of patients may improve if clozapine is used for up to 6 months. This, in combination with clozapine’s adverse-effects profile, provides sufficient information to conclude that clozapine is not a panacea for schizophrenia. Polydipsia and hyponatremia (psychogenic water drinking) is a frequent problem among treatment-resistant patients, and clozapine reportedly decreases water drinking and increases serum sodium in such patients.

Because of the risk of orthostatic hypotension, clozapine is usually titrated more slowly than other antipsychotics, particularly on an outpatient basis. If a 12.5-mg test dose does not produce hypotension, then clozapine 25 mg at bedtime is recommended, increased to 25 mg twice a day after 3 days, and then increased in 25- to 50-mg/day increments every 3 days until a dose of at least 300 mg/day is reached. Because high doses are associated with significantly increased side effects, including seizures, a clozapine serum concentration is recommended before exceeding 600 mg/day. If the clozapine serum concentration is less than 350 ng/mL (350 mcg/L; 1.07 μmol/L), then the dose should be increased as side effects allow to achieve this serum concentration.

Augmentation and Combination Strategies

Little empirical evidence exists to guide treatment decisions for patients who do not respond to clozapine. A small number of randomized trials have examined the efficacy of clozapine augmentation with SGAs, and the results have been more negative than positive (see Fig. 76–1). Augmentation therapy involves the addition of a nonantipsychotic drug to an antipsychotic drug in a poorly or partially responsive patient, whereas combination treatment involves using two antipsychotics simultaneously. Several guidelines should be followed regarding augmentation: (a) augmentation should be used only in inadequately responding patients; (b) augmentation agents are rarely effective for schizophrenic symptoms when used alone; (c) augmentation responders usually improve rapidly; and (d) if augmentation does not improve symptomatology, the augmenting agent should be discontinued.

Mood stabilizers are frequently used as an augmentation strategy. Lithium does not enhance antipsychotic effect but may improve labile affect and agitated behavior in selected patients. Valproic acid and carbamazepine have also been used. A large placebo-controlled trial supports faster symptom improvement, but no difference in maintenance treatment, when divalproex was used in combination with either olanzapine or risperidone. Enzyme induction with carbamazepine can cause a decrease in antipsychotic serum concentrations and potentially worsen psychotic symptoms in some patients. The 2009 PORT recommendations do not endorse the use of mood stabilizer augmentation in treatment-resistant patients.

Selective serotonin reuptake inhibitors (SSRIs), particularly fluoxetine and fluvoxamine, have reasonable evidence for improving negative symptoms when used as augmentation of FGAs. Potential benefits of combining SSRIs with SGAs require more study. Consistently positive results have been reported when using SSRIs to treat obsessive-compulsive symptoms that worsen or arise during clozapine treatment.

Combining an FGA with an SGA and combining different SGAs have been suggested as intervention strategies for treatment-resistant patients. Pharmacodynamically, no rationale exists for explaining how combinations of antipsychotics would produce enhanced efficacy, and increased side effects, particularly increased EPS, metabolic effects, and hyperprolactinemia are possible results. Clinically, no evidence exists to prove that antipsychotic combinations are superior to monotherapy, and the 2009 PORT recommendations do not support their use. In general, a series of antipsychotic monotherapies, including clozapine, are preferred over antipsychotic combinations. However, when clozapine fails to produce desired outcomes, a time-limited combination trial is sometimes recommended (see Fig. 76–1, stages 4 or 6). Such antipsychotic combination treatment trials should be time limited (12 weeks) and the patient carefully evaluated with rating scales for changes in symptomatology. If no apparent improvement is observed, then one of the medications should be tapered and discontinued. However, if the patient has a partial response (greater than or equal to 20% improvement in positive symptoms) after 12 weeks with combination treatment in stages 4 or 6, medications should be titrated to doses at the upper end of the therapeutic range, and treatment should continue for an additional 12 weeks before a change in stage is considered.
CHAPTER 76

ANTIPSYCHOTIC DRUG MECHANISMS OF ACTION

The exact mechanism of action of antipsychotics is unknown. It has been suggested that antipsychotics be classified into three different categories: (a) typical or traditional (high D₂ antagonism and low 5-HT₂A antagonism); (b) atypical (moderate to high D₂ antagonism and high 5-HT₂A antagonism); and (c) atypical clozapine-like (low D₂ antagonism and high 5-HT₂A antagonism). With the exception of aripiprazole, all current SGAs have a greater affinity for 5-HT₂A receptors than D₂ receptors.

Studies of antipsychotic receptor binding in humans have used PET scans to examine neurotransmitter receptor binding at steady-state, 12 hours post dose in small numbers of individuals. At least 60% to 65% D₂ receptor occupation is necessary to decrease positive psychotic symptoms, whereas blockade of approximately 77% or more of D₂ receptors is associated with EPS. FGAs are dopamine receptor antagonists with high affinity for D₂ receptors. During chronic treatment with these agents, between 70% and 90% of D₂ receptors in the striatum are usually occupied. In contrast, during clozapine treatment only 38% to 47% of D₂ receptors are occupied, even with high doses. Newer SGAs have variable D₂ binding. With low-dose risperidone (2–5 mg/day), D₂ binding ranges from 60% to 79%, but with doses greater than 6 mg daily, binding commonly exceeds the 77% threshold associated with the development of EPS. Risperidone 2 mg/day produces 5-HT₂A binding greater than 70%, and with 4 mg/day it is nearly 100%. Olanzapine 10 to 20 mg/day produces D₂ binding ranging from 71% to 80%, whereas at 30 to 40 mg/day, it ranges from 83% to 88%. At 5 mg/day, 5-HT₂A receptors are near saturation of binding. Ziprasidone has the highest 5-HT₂A/D₂ affinity ratio of any of the currently available antipsychotics. It is also a potent 5-HT₂A agonist.

Quetiapine has the lowest D₂ binding. At doses of 300 to 600 mg/day, D₂ binding ranges from 0% to 27%. Even at quetiapine 800 mg/day, only 30% of D₂ receptors are occupied. At these same daily doses, 45% to 90% of 5-HT₂A receptors are occupied. However, when quetiapine D₂ binding is examined 2 to 3 hours post dose, 58% and 64% of receptors were occupied with 400 mg and 450 mg, respectively. Transient blockade of dopamine receptors may be adequate to produce antipsychotic effect, but long-term D₂ blockade is required for production of EPS and sustained hyperprolactinemia. Low D₂ binding, and thus atypicality, can be directly associated with how rapidly the antipsychotic dissociates from the D₂ receptor. The availability of aripiprazole, a partial agonist at D₂ receptors, represents a further elaboration of the dopamine hypothesis of antipsychotic action. It is proposed that aripiprazole works as a functional partial agonist. Aripiprazole is a rather weak 5-HT₂A agonist but a potent 5-HT₆ agonist.

Iloperidone has high affinity for D₂, D₃, and 5-HT₂A receptors, and moderate affinity for D₄, 5-HT₆, 5-HT₇, and 5-HT₁D receptors. Iloperidone has high affinity for 5-HT₂A and D₂ receptors as well as for 5-HT₆ and histamine-1 receptors. D₂ occupancy of approximately 80% is predicted to occur with a sublingual dose of 5 to 10 mg twice daily. It is clear that the SGAs differ in their mechanisms of action and most likely in the manner in which they produce an atypical clinical profile.

The primary therapeutic effects of FGAs are thought to occur in the limbic system, including the ventral striatum, whereas EPS are thought to be related to DA blockade in the dorsal striatum. 5-HT₂A antagonism in combination with modest D₂ blockade leads to release of dopamine in the prefrontal cortex, and this is one explanation for the decrease in negative symptoms and improvement in cognition reported with atypical antipsychotics.

Antipsychotics vary in their effects on other neurotransmitter receptor systems. Although the significance of these different mechanisms on efficacy is unclear, they do potentially explain differences in side-effect profiles. These differences in pharmacodynamic profiles point out that the SGAs are not all alike, and patients obtaining an inadequate clinical response (either efficacy or side effects) with one antipsychotic may have a superior response on an alternate drug. Thus serial SGA monotherapy trials should be tried in patients receiving a suboptimal clinical response (see Fig. 76–1).

PHARMACOKINETICS

As a class, antipsychotics are highly lipophilic and highly bound to membranes and plasma proteins. They distribute readily into most tissues with a high blood supply and can accumulate in tissues; therefore they have large volumes of distribution. Most antipsychotics are largely metabolized, primarily through the cytochrome P450 (CYP) pathways in the liver, except for ziprasidone, which is largely metabolized by aldehyde oxidase. Fluphenazine, perphenazine, and risperidone are metabolized through CYP2D6, and thus are susceptible to polymorphic metabolism. This is also one of the major pathways for the metabolism of iloperidone. Thirty percent to 35% of Africans and Asians are slow to intermediate metabolizers, and approximately 0% to 5% of African Americans, 1% of Asians, and 0% to 5% of Caucasians are poor metabolizers. In addition, some populations of patients, those from Ethiopian or Swedish descent in particular, may be ultra-rapid metabolizers. Polymorphism in CYP1A2 can potentially result in a decrease in the metabolic rate of clozapine, and increased clozapine metabolic rate in smokers has been linked to a specific genotype. The possibility of genetic polymorphism should be considered when dosing and monitoring the clinical effects of antipsychotics.

Table 76–6 outlines the prominent metabolic pathways of selected antipsychotics.

Asenapine is unique in that it has less than 2% bioavailability after oral administration, but has a bioavailability of approximately 35% sublingually—the FDA approved route of administration. Eating and drinking within 10 minutes after sublingual administration will reduce bioavailability.

Most antipsychotics have fairly long elimination half-lives, generally 24 hours or more, with the exception of quetiapine and ziprasidone, which have short half-lives. Among the SGAs, only clozapine has an established therapeutic serum concentration, with efficacy being associated with a clozapine plasma concentration greater than 350 ng/mL (350 mcg/L; 1.07 μmol/L). Whether a potential maximum therapeutic clozapine serum concentration exists is unknown. Clozapine serum concentration should be obtained before exceeding 600 mg daily; in patients who develop unusual or severe adverse side effects; in patients who are taking concomitant medications that can cause drug interactions; in patients who have age or pathophysiologic changes suggesting a change in pharmacokinetics; or for assessment of patient adherence.

Long-acting risperidone is a suspension of drug in glycolic acid-lactate copolymer microspheres. After IM injection the polymer is sesame seed oil for deep intramuscular injection. Their absorption after oral administration, but has a bioavailability of approximately 35% sublingually—the FDA approved route of administration. Eating and drinking within 10 minutes after sublingual administration will reduce bioavailability.

associated with different drugs should be reevaluated. As we learn more about relative side-effect risks (e.g., weight gain, glucose intolerance, QTc prolongation, acute EPS, and tardive dyskinesia), it will be necessary to regularly reconsider which antipsychotics should be considered first-line treatment alternatives.

Endocrine System

DA blockade in the tuberoinfundibular tract results in increased prolactin levels as DA is the major prolactin-inhibiting factor. Hyperprolactinemia may occur in up to 87% of patients treated with FGAs, risperidone or paliperidone. The major side effects associated with hyperprolactinemia are gynecomastia, galactorrhea, menstrual irregularities, decreased libido, and sexual dysfunction. Although not conclusive, chronic hyperprolactinemia has been associated with decreased bone density. Tolerance does

ARDS EFFECTS

Table 76-7 presents the relative incidence of common categories of antipsychotic side effects. Side effects are discussed below with respect to organ system affected. A general approach to monitoring and assessing side effects requires prospective monitoring by clinicians, preferably using a thorough review of systems approach. Patient-oriented self-rated side-effect scales can be helpful, as many patients with schizophrenia do not readily complain of side effects.

With the variety of antipsychotics currently available, using an alternative medication should be considered in patients who complain of poorly tolerated side effects. Because medication side effects are one of the primary predictors of patient nonadherence, the clinician should take advantage of the treatment options currently available in an attempt to improve patient outcomes. As new antipsychotics become available, side effects and risks associated with different drugs should be reevaluated. As we learn more about relative side-effect risks (e.g., weight gain, glucose intolerance, QTc prolongation, acute EPS, and tardive dyskinesia), it will be necessary to regularly reconsider which antipsychotics should be considered first-line treatment alternatives.

moter region polymorphism of the 5-HT 2C receptor gene confirmed meta-analysis of all genetic studies looking at the −759 C/T pro-
the drug.  69

patient gains more than 5% of baseline body weight after starting force recommends consideration of a change in antipsychotic if a
modification programs are reported to be successful in small short-
to cause weight gain, dietary restriction, exercise, and behavior be discouraged. Switching patients to antipsychotics less likely
be associated with minimal weight gain.
The clinical significance of weight gain during antipsychotic therapy is substantial. The risk of cardiovascular-related mortality is higher in individuals with schizophrenia, and this is further aggravated by drug-related weight gain and the high prevalence of smoking. Additionally, obesity is a risk factor for diabetes mellitus. Weight gain during treatment is a major reason for poor patient medication adherence, and patients commonly report weight gain as being a concern. Several different genetic variations have been correlated with predisposition for antipsychotic-associated weight gain. Recent meta-analysis of all genetic studies looking at the −759 C/T promoter region polymorphism of the 5-HT 2C receptor gene confirmed an association of 5-HT 2C in antipsychotic-induced weight gain. Polymorphisms in leptin and leptin receptor genes have also been linked with clozapine and olanzapine-associated weight gain. Alfa-2a-adrenergic receptor gene, G protein beta-3 subunit gene, and brain-derived neurotrophic factor (BDNF) gene have been genetic targets; however, results are inconsistent as to whether a relationship exists with these polymorphisms and antipsychotic-associated weight gain. A number of pharmacologic interventions have been attempted for antipsychotic-related weight gain, but in general these should be discouraged. Switching patients to antipsychotics less likely to cause weight gain, dietary restriction, exercise, and behavior modification programs are reported to be successful in small short-term studies. An American Diabetes Association consensus task force recommends consideration of a change in antipsychotic if a patient gains more than 5% of baseline body weight after starting the drug. Schizophrenic patients have a higher prevalence of type 2 diabetes than the nonschizophrenic population. Beyond this, antipsychotics may adversely affect glucose levels in diabetic patients. The extent to which these effects are related to drug-induced weight increase is unclear. Data collected from the FDA MedWatch Drug Surveillance System for clozapine, olanzapine, quetiapine, and risperidone indicate that nearly 60% of the new-onset diabetes reported occurred within the first 6 months of treatment initia-
tion. Olanzapine has the highest risk of new-onset diabetes followed by risperidone and then quetiapine. Although likely less than with the other SGAs, inadequate data are available to accurately estimate the risk with ziprasidone and aripiprazole. Clozapine likely poses a risk at least as great as with olanzapine. The 2009 PORT recommendations do not recommend olanzapine as a first line antipsychotic option. In March 2004, the FDA issued a safety alert requiring revisions in the labeling of all SGAs that describes the increased risk of diabetes mellitus in patients taking atypical antipsychotics. Given the public health significance of diabetes, clarifying the diabetogenic effect of SGAs is a major focus of current research. Moreover, designing care models and standards for managing diabetes in patients with schizophrenia is another major consideration.

CLINICAL CONTROVERSY

The relative risk of diabetes mellitus versus the risk of EPS associated with different antipsychotics makes individual antipsychotic choice challenging. This is particularly true given that olanzapine causes the most weight gain and appears to have the highest risk of precipitating diabetes mellitus (except for clozapine), but yet research does show some modest benefits with regard to efficacy.

Cardiovascular System

Orthostatic Hypotension Postural or orthostatic hypotension, defined as a greater than 20-mm Hg drop in systolic pressure, is caused by α-adrenergic blockade, and may occur in up to 75% of treated patients. Antipsychotics with a greater risk should have their doses titrated over several days to decrease the risk of symptomatic hypotension. Antipsychotic combination treatment may result in a greater risk of orthostasis. Orthostatic hypotension can occur in any patient, but diabetic patients with preexisting cardiovascular disease and the elderly seem particularly predisposed. Patients should be advised to slowly move to the standing position to allow for adaptation. Tolerance to this effect may occur within 2 to 3 months. If not, lower doses or a change to an antipsychotic with less α-blockade can be attempted.

Electrocardiographic Changes Among the antipsychotics, thioridazine, clozapine, iloperidone, and ziprasidone are most likely to cause electrocardiogram (ECG) changes. ECG changes include increased heart rate (through sinus tachycardia from anticholinergic effects, or reflex tachycardia from α-adrenergic blockade), flattened T waves, ST segment depression, and prolongation of QT and PR intervals. The most clinically important of these potential changes is prolongation of the QTc, which has been associated with ventricular arrhythmias, including torsades de pointes syndrome. Thioridazine has been shown to prolong the QTc on average approximately 20 milliseconds (msec) longer than haloperidol, risperidone, or quetiapine. Thioridazine's effects on QTc prolongation is dose related, and has led to a black box warning in the FDA-approved product labeling. In the same study, ziprasidone prolonged the QTc on average approximately 10 msec longer or about one-half of the effect of thioridazine. Widespread clinical use suggests that ziprasidone's effects on the ECG are not associated with clinical sequelae, unless the patient has baseline risk factors. Iloperidone has a dose-related effect on QTc, with an average prolongation of about 9 msec at a dose of 20 to 24 mg/day. Although the precise point at which QTc prolongation becomes clinically dangerous is unclear, it has been recommended to discontinue a medication associated with QTc prolongation if the interval consistently exceeds 500 msec.

Greater caution regarding antipsychotic choice and use is necessary in the elderly, in patients with preexisting cardiac or cerebrovascular disease, and in patients taking diuretics or medications that may prolong the QTc. In patients older than 50 years of age, a pretreatment ECG is recommended, as are baseline serum potassium and magnesium levels. These factors should be considered in antipsychotic selection.
Sudden Cardiac Death A recent, large retrospective analysis found risk of sudden cardiac death with current use of FGAs and SGAs was twice that of nonusers of antipsychotics, with risk increasing with escalated dose. Further meta-analysis has conferred a lack of evidence for differential effects on cardiovascular mortality favoring one class of antipsychotics over the other. Further prospectively designed studies are needed to confirm a dose-dependent increase in cardiovascular sudden death with current antipsychotic use, and also to determine whether certain antipsychotics are associated with a greater risk than others.

Lipid Changes Treatment with at least some SGAs and phenothiazines appears associated with elevations in serum triglycerides and cholesterol. Oxidation of apolipoprotein B lipoproteins and elevations in sterol regulatory element binding protein-controlled gene expression, are among the purported mechanisms by which these lipid changes occur during antipsychotic treatment. Among the SGAs, less risk for change in serum lipid or cholesterol levels can occur with risperidone, ziprasidone, or aripiprazole. In the CATIE trial, olanzapine was associated with greater and significant adverse effects on metabolic parameters, including lipids, blood glucose, and body weight versus the other study treatments, but these differences in tolerability did not affect discontinuation rates.

The occurrence of weight gain, diabetes, and lipid abnormalities during antipsychotic therapy is consistent with the development of metabolic syndrome (i.e., syndrome X). Cohorts of patients with schizophrenia have shown elevated prevalence of metabolic syndrome as compared with general population cohorts. Prevalence rates of metabolic syndrome in U.S. populations range from 28% to 60%, with 40.9% reported in the prospectively designed CATIE trial.

Metabolic syndrome consists of raised triglycerides (greater than or equal to 150 mg/dL [1.7 mmol/L]), low HDL cholesterol (less than or equal to 40 mg/dL [1.03 mmol/L]) for males, less than or equal to 50 mg/dL [1.29 mmol/L] for females), elevated fasting glucose (greater than or equal to 100 mg/dL [5.6 mmol/L]), blood pressure elevation (greater than or equal to 130/85 mm Hg), and weight gain (abdominal circumference greater than 102 cm [40 in] for males, greater than 88 cm [34 in] in females). These abnormalities dictate an important role for general health screening and monitoring in patients with schizophrenia, and prompt intervention when such abnormalities occur. The propensity of individual antipsychotics to produce metabolic disturbances should be considered in the context of individual patient risk factors at the time of drug selection.

Autonomic Nervous System

Patients receiving antipsychotics or antipsychotics in combination with anticholinergics, can experience anticholinergic side effects (e.g., dry mouth, constipation, tachycardia, blurred vision, inhibition or impairment of ejaculation, urinary retention, or impaired memory). This is particularly so with low-potency FGAs, and the elderly are especially sensitive to these effects. Of the SGAs, clozapine and olanzapine have moderately high rates of causing anticholinergic effects. Constipation, caused by slowed peristaltic movement and decreased intestinal fluid content, should be closely monitored and treated, especially in the elderly. Paralytic ileus and necrotizing enterocolitis can also occur.

Central Nervous System

Extrapyramidal System

Dystonia. Dystonia is a state of abnormal tonicity, sometimes described simplistically as a severe “muscle spasm.” More accurately, they are prolonged tonic contractions, with a rapid onset, usually within 24 to 96 hours of dosage initiation or dosage increase. They can be life-threatening, as in the case of pharyngeal-laryngeal dystonias, and can contribute to patient nonadherence. Types of dystonic reactions include trismus, glossospasm, tongue protrusion, pharyngeal-laryngeal dystonia, blepharospasm, oculogyric crisis, torticollis, and retrocollis. Dystonic reactions occur primarily with FGAs. Risk factors include younger patients (especially males), the use of high-potency agents, and high dosage. The overall incidence from the 1960s through the mid-1970s ranged from 2.3% to 10%, but as higher-potency traditional antipsychotics became more widely used, the rate increased to as high as 64%.

Intramuscular or intravenous anticholinergics (Table 76–8) or benzodiazepines are the treatments of choice for dystonia. Benzotropine mesylate 2 mg or diphenhydramine 50 mg can be given intramuscularly or intravenously. Diazepam 5 to 10 mg by slow IV push or lorazepam 1 to 2 mg intramuscularly are treatment alternatives. Relief is typically seen within 15 to 20 minutes of an intramuscular injection and within 5 minutes of intravenous administration. The antipsychotic can be continued, with concomitant short-term use of oral anticholinergic agents. In general, prophylactic anticholinergic medications are not recommended routinely with all FGAs. However, prophylaxis is reasonable when using high-potency FGAs (e.g., haloperidol or fluphenazine) in young men, and in patients with a history of dystonia. Dystonias can also be minimized by the use of lower initial FGA doses. Anticholinergics are good choices for prophylaxis, whereas amantadine has not been proven effective for this purpose. The risk of dystonia is greatly reduced with SGAs. Akathisia. Akathisia is defined as the inability to sit still and as being functionally motor restless. The most accurate diagnosis is made by combining subjective complaints with objective symptoms (pacing, shifting, shuffling, or tapping feet). Subjectively, patients may describe a feeling of inner restlessness or disquiet or a compulsion to move or remain in constant motion. Akathisia occurs in 20% to 40% of patients treated with high-potency FGAs. Akathisia is frequently accompanied by dysphoria.

Akathisia responds poorly to anticholinergics. Traditionally, reduction in antipsychotic dosage has been considered the best intervention; however, this might not be a realistic goal in an acutely psychotic patient. A logical alternative is to switch to an antipsychotic with a lower risk of akathisia, or an antipsychotic previously used in the patient without adverse effect. Akathisia can occasionally occur with SGAs. Quetiapine and clozapine appear to have the lowest risk of producing akathisia.
Benzodiazepines have been used for treatment of akathisia, but the high prevalence of co-occurring substance abuse in schizophrenia discourages their prescribing. The β-blockers (e.g., propranolol in doses up to 160 mg daily, nadolol in doses up to 80 mg daily, and metoprolol in β₂-selective doses of 100 mg daily or less) are reported as effective.

**Pseudoparkinsonism.** Pseudoparkinsonism, produced by D₂ blockade in the nigrostriatum, resembles idiopathic Parkinson disease. A patient with pseudoparkinsonism can present with any of four cardinal symptoms: (1) akinesia, bradykinesia, or decreased motor activity including difficulty initiating movement, as well as extreme slowness, mask-like facial expression, micrographia, slowed speech, and decreased arm swing; (2) tremor, known as pill-rolling type, that is predominant at rest and decreases with movement, usually involving the fingers and hands, although tremors can also be seen in the arms, legs, neck, head, and chin; (3) cogwheel rigidity, seen as the patient’s limbs yielding in jerky, ratchet-like fashion when passively moved by the examiner; and (4) postural abnormalities and instability manifested as stooped posture, difficulty in maintaining stability when changing body position, and a gait that ranges from slow and shuffling to festinating. Fatigue and weakness can be noted, as well as oral abnormalities including dysphagia, dysarthria, and abnormal palomental and glabellar reflexes. The overall incidence of pseudoparkinsonism from FGAs ranges from 15.4% to 36%, depending on the drug and dose. Akinesia alone can be seen in 59% of patients on high-potency FGAs. Other risk factors include increasing age and possibly female gender. The onset of symptoms is typically 1 to 2 weeks after initiation of antipsychotic therapy or a dose increase.

The efficacy of anticholinergic medications in treating symptoms of pseudoparkinsonism is well established. Benztprine’s long half-life allows once- to twice-daily dosing. Typical dosing is 1 to 2 mg twice a day up to a usual maximum dosage of 8 mg daily, although some patients will continue to respond to doses up to 12 mg. Trihexyphenidyl (2–5 mg 3 times a day), diphenhydramine (25–50 mg 3 times a day), and biperiden (2 mg 3 times a day) usually require thrice-daily administration. Diphenhydramine produces more sedation than the other agents. All of the anticholinergics have been abused for their euphoriant effects. Symptoms typically begin to resolve within 3 to 4 days after initiation of treatment, but a minimum of at least 2 weeks of treatment is normally required for full response. Amantadine is generally as efficacious for pseudoparkinsonism as anticholinergics, with significantly less effect on memory function. The need for prophylactic use of these agents against pseudoparkinsonism is less convincing than with dystonias, and is sometimes irreversible and continues to be a controversial issue.

**Tardive Dyskinesia.** Tardive dyskinesia is a syndrome characterized by abnormal involuntary movements occurring late in onset in relation to initiation of antipsychotic therapy. Tardive dyskinesia is sometimes irreversible and continues to be a controversial issue.

The classic description of tardive dyskinesia is the buccal-lingualmasticatory (BLM) syndrome, or orofacial movements. The onset of BLM movements is usually insidious. Typically, they are the first detectable signs of tardive dyskinesia and begin with mild forward, backward, or lateral movements of the tongue. As the disorder progresses, more obvious or frank BLM movements appear, including tongue thrusting, rolling, or fly-catching movements, and chewing or lateral jaw movements. Tardive dyskinesia symptoms can interfere with the patient’s ability to chew, speak, or swallow. Further complications include oral ulcerations, inability to wear dentures, and inflammation and loosening of mandibular joints. Eating difficulties and malnutrition can be severe complications. Weight loss can be seen in patients with esophageal or respiratory manifestations but not in those with truncal movements. Facial movements include frequent blinking, brow arching, grimacing, upward deviation of the eyes, and lip smacking. Involvement of the extremities sometimes occurs, with the appearance of restless choreiform and distal athetosis of limbs including twisting, spreading, flexion and extension of fingers, toe tapping, and toe dorsiflexion. Unusual posture, hyperextension, pelvic thrusting, axial hyperkinesia ballismus, exaggerated lordosis, rocking, and swaying are occasionally observed. Among the differential diagnoses are withdrawal dyskinesias occurring after short-term use of antipsychotics, spontaneous orofacial dyskinesias in the elderly, orofacial dyskinesias in the edentulous, stereotypic movements in schizophrenics, Huntington disease, and congenital torsion dystonia. Orofacial movements are more common in older patients, whereas the truncal axial movements are classically reported in young adults. Movements can worsen with stress, decrease with sedation, and disappear during sleep. Concentration on motor tasks or attempts to suppress the movements can actually increase them.

Early signs of tardive dyskinesia can be reversible but if allowed to persist they can become irreversible, even with drug discontinuation. When the antipsychotic dose is decreased or tapered and discontinued, worsening of abnormal movements can occur, followed by possible slow improvement after months or years if the patient remains on lower doses or discontinues treatment. No standardized diagnostic criteria for tardive dyskinesia are available. Abnormal involuntary movements can be detected early through physical assessment and the use of rating scales. Available rating scales include the Abnormal Involuntary Movements Scale (AIMS) and the Dyskinesia Identification System: Condensed User Scale (DISCUS). Neither scale is diagnostic in itself.

Risk factors include increasing age, the occurrence of acute EPS, poor antipsychotic drug response, diagnosis of organic mental disorder, diabetes mellitus, mood disorders, and possibly female gender. Duration of antipsychotic therapy, daily dosage, and possibly total cumulative dosage are probably the most significant risk factors. Polymorphisms of the dopamine D₃ receptor, 5-HT₂C receptor, and the superoxide dismutase-2 genes have all been implicated in varying the risk of TD with antipsychotic use. Overall morbidity and mortality are greater in tardive dyskinesia patients.

With FGAs, the reported incidence of tardive dyskinesia ranges from 0.5% to 62%, with an estimated incidence of about 5% per year in nonelderly (<65 years) adults and 5.3% per year in the elderly (≥65 years). For individual agents, the annual incidence rates ranged from zero to 0.5% for olanzapine to 0.6% to 0.7% for risperidone or quetiapine. To date, there are no reports of tardive dyskinesia with clozapine monotherapy.

Prevention of tardive dyskinesia is important, as treatment of the movements once they occur is difficult. One of the more compelling
arguments for the first-line use of SGAs is their lower risk of tardive dyskinesia, switching to clozapine has decreased abnormal involuntary movements. Switching antipsychotic therapy to clozapine is a favored first-line pharmacotherapeutic strategy, particularly in patients with moderate to severe dyskinesia.

Numerous drugs have been used in an attempt to treat tardive dyskinesia. In two controlled trials lasting 22 to 52 weeks, clozapine decreased abnormal involuntary movements. Switching antipsychotic therapy to clozapine is a favored first-line pharmacotherapeutic strategy, particularly in patients with moderate to severe dyskinesia.

**Sedation and Cognition**

Chlorpromazine, thioridazine, mesoridazine, clozapine, olanzapine, and quetiapine are the most sedating antipsychotics. Administration of most or all of the daily dosage at bedtime can decrease daytime sedation and in some patients eliminate the need for hypnotic agents. Sedation occurs early in treatment and can decrease over time. Oversedation can play a large role in cognitive, perceptual, and motor dysfunction. However, positive effects of medication on cognition are seen with chronic administration, evidenced by improvements in tasks involving visual-motor skills, attention to task, and working memory. Compared with FGAs, several studies have shown cognitive benefits of SGAs. However, results from the CATIE trial showed no differences in cognitive improvement between SGAs and the FGA perphenazine. Comparative effects of different SGAs on cognition are as yet unclear, but available studies suggest that different SGAs can have effects on varying cognitive domains. An algorithm-driven disease management program was shown to improve cognition over a 9-month period.

**Seizures**

An increased risk of drug-induced seizures occurs in all patients treated with antipsychotics. However, this risk is greater if the following predisposing factors are present: preexisting seizure disorder, history of drug-induced seizure, abnormal electroencephalogram (EEG), and preexisting CNS pathology or head trauma. Seizures are more closely associated with the use of higher doses, rapid dosage increases, and on initiation of treatment. When an isolated seizure occurs, a dosage decrease is first recommended; anticonvulsant therapy is not recommended. Although spontaneously occurring seizures have been reported with most antipsychotics, the highest potential risk for an antipsychotic-related seizure is with clozapine or chlorpromazine. If a change in antipsychotic therapy is required because of a drug-induced seizure, risperidone, molindone, thioridazine, haloperidol, pimozide, trifluoperazine, and fluphenazine are associated with the lowest potential.

**Thermoregulation**

Poikilothermia, the body temperature adjusting to the ambient temperature, can be a serious side effect of antipsychotic therapy in temperature extremes. Hyperpyrexia can be a danger in hot weather or during exercise. Inhibition of sweating, a result of anticholinergic properties impairing the peripheral mechanisms of heat dissipation, can also contribute to this problem, which in its severest form can lead to heat stroke. Hypothermia is also a risk, particularly in the elderly (≥65 years) and in cold climates. All patients receiving antipsychotics should be educated about these potential problems. Thermoregulatory problems are reportedly more common with the use of low-potency FGAs and can occur with the more anticholinergic SGAs.

**Neuroleptic Malignant Syndrome**

Neuroleptic malignant syndrome (NMS) occurs in 0.5% to 1% of patients receiving FGAs. The rate of NMS has diminished since the introduction of SGAs, and reliable current estimates of the incidence with SGAs are not available. NMS can occur more frequently in patients receiving high-potency FGAs, injectable or depot FGAs, and in patients who are dehydrated, with physical exhaustion, or organic mental disorders. Although less common, NMS has been reported with SGAs, including clozapine. The onset of symptoms varies from early in treatment to months later. It develops rapidly, over the course of 24 to 72 hours. NMS can occur after antipsychotic discontinuation, especially when depot agents are used. Possible mechanisms of NMS include disruption of the central thermoregulatory process or excess production of heat secondary to skeletal muscle contractions. The differential diagnosis includes heat stroke, lethal catatonia, anesthetic-associated malignant hyperthermia, anticholinergic toxicity, and monoamine oxidase inhibitor drug interactions. Cardinal signs and symptoms of NMS are body temperature exceeding 38°C (100.4°F), altered level of consciousness, autonomic dysfunction (tachycardia, labile blood pressure, diaphoresis, tachypnea, or urinary or fecal incontinence), and rigidity. Laboratory evaluation, although nonspecific, frequently shows leukocytosis with or without a left shift, increases in creatine kinase (CK), aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and myoglobinuria.

Treatment should begin with antipsychotic discontinuation and supportive care. In many cases that alone is effective. The role of adjunctive agents is unclear, yet they are often used. The DA agonist bromocriptine reduces rigidity, fever, or CK in up to 94% of patients, whereas the use amantadine has been successful in up to 63% of patients. Dantrolene has been used as a skeletal muscle relaxant, with effects on temperature, heart rate, respiratory rate, and CK in up to 81% of patients. Wide recognition and rapid antipsychotic discontinuation has drastically reduced mortality from 20% 25 years ago to 4% in the mid-1990s. Many patients with schizophrenia, despite having had NMS, will require future antipsychotic pharmacotherapy. A review of antipsychotic rechallenges suggests that the risk of rechallenge is acceptable in most patients, provided that the patient is observed for an extended period of time (2 weeks or more is suggested) without antipsychotics, that there is careful monitoring and slow dose titration, and that the patient is maintained on the lowest possible dose. A different antipsychotic, a SGA or a low potency FGA, should be used for rechallenge following an episode of NMS.

**Psychiatric Side Effects**

Antipsychotic-induced akathisia, akinesia, and dysoria can have unfortunate sequelae, resulting in what has been termed “behavioral toxicity.” Akinesia, characterized by “diminished spontaneity,” results in symptoms of apathy and withdrawal, often mistaken for the negative symptoms of schizophrenia; these patients can actually appear depressed. Delirium and psychosis are reported with larger doses of FGAs or combinations of anticholinergics with FGAs. Chronic confusion and disorientation can occur in the elderly as a result of antipsychotic treatment. Unfortunately, the link is not always made with antipsychotic therapy, and the patient is misdiagnosed with an delirium from a different etiology. This clinical presentation, called a pseudodementia, may be reversible on discontinuation of the antipsychotic.

**Ophthalmologic Effects**

Anticholinergic effects of antipsychotics or concomitant antiparkinson medications can exacerbate narrow-angle (angle closure) glaucoma. Antipsychotics with low anticholinergic effects should be used in such individuals, and they should be appropriately monitored.

Opaque deposits in the cornea and lens occur with chronic phenothiazine treatment, most frequently with chlorpromazine. Although visual acuity is not usually affected, periodic slit-lamp ophthalmologic examinations are frequently recommended in patients receiving long-term treatment with phenothiazines, as fully formed cataracts are a possibility.
Because of cataract development and lenticular changes in animals, baseline and periodic eye examinations are recommended in the product labeling for quetiapine.\textsuperscript{91} However, clinical use of quetiapine since marketing has not shown a significant risk of cataracts.\textsuperscript{2,91} Retinitis pigmentosa can result from use of thioridazine doses greater than 800 mg daily. It is caused by melanin deposits and can result in permanent visual impairment or blindness.

### Genitourinary System

Urinary hesitancy and retention is reported with low-potency FGAs and with clozapine. Anticholinergic effects cause smooth muscle slowing and paralyze the detrusor muscle of the bladder, requiring greater urine volume to evoke muscle contraction. Men with benign prostatic hypertrophy are especially prone to this effect.\textsuperscript{92}

Urinary incontinence is thought to be caused by \(\alpha\)-blockade, and among the SGAs, it appears to be particularly problematic with clozapine. The incidence has been reported to be as high as 44%, and it can be persistent in 25% of patients.\textsuperscript{93}

Numerous mechanisms may result in sexual dysfunction, including dopaminergic blockade, hyperprolactinemia, histaminergic blockade (sedation), anticholinergic effects, and \(\alpha\)-adrenergic blockade. Although inadequately studied, multiple mechanisms are likely responsible for sexual dysfunction. Unmedicated individuals with schizophrenia report decreased libido. Most but not all studies show a relationship between hyperprolactinemia and sexual dysfunction, including decreased libido, erectile dysfunction, difficulty achieving orgasm, and ejaculatory abnormalities. Although risperidone produces at least as much sexual dysfunction as FGAs, other SGAs, which have weak effects on prolactin, produce less sexual dysfunction. It is unclear whether hyperprolactinemia directly impairs sexual functioning, reflects high dopaminergic blockade from risperidone and FGAs, or is associated with other mechanisms of producing sexual dysfunction. Patients experiencing sexual dysfunction with FGAs or risperidone should be switched to an SGA with less effect on prolactin.\textsuperscript{94}

### Hematologic System

Transient leukopenia can occur during initial treatment with antipsychotics; however, it typically does not progress to clinically significant parameters.\textsuperscript{95} The three antipsychotics with highest relative risk of neutropenia are in rank order clozapine, chlorpromazine, and olanzapine.\textsuperscript{96} If the WBC count is less than 3,000/mm\(^3\) \((3 \times 10^9/L)\), or if the absolute neutrophil count (ANC) is less than 1,000/mm\(^3\) \((1 \times 10^9/L)\), the antipsychotic should be discontinued, and the WBC monitored closely until it returns to normal. Agranulocytosis reportedly occurs in 0.01% of patients receiving FGAs, and more frequently with chlorpromazine and thioridazine. The onset is usually within the first 8 weeks of therapy. Agranulocytosis can initially manifest as a local infection, with sore throat, leukoplakia, erythema, and ulcerations of the pharynx. These symptoms in any patient receiving antipsychotics should signal the immediate need for a WBC count. If either the WBC count or ANC falls below these parameters, the drug should be discontinued immediately and the patient monitored closely for the development of secondary infections. Isolated rare cases of thrombocytopenia and cosinophilia have been reported.

Agranulocytosis with clozapine significantly limits the usefulness of this agent. Data reveal that the risk of developing neutropenia or agranulocytosis with clozapine is approximately 3% and 0.8%, respectively.\textsuperscript{96} Increasing age and female gender are associated with greater risk. The time period for greatest risk is between months 1 and 6 of treatment, and weekly WBC monitoring for the first 6 months of therapy is mandated in the FDA-approved product labeling. After the first 6 months, the labeling allows the frequency of WBC monitoring to be decreased to every 2 weeks for months 7 through 12, after which it can be decreased to monthly if all WBCs are normal. If the total WBC count drops to less than 2,000/mm\(^3\) \((2 \times 10^9/L)\), or the ANC is less than 1,000/mm\(^3\) \((1 \times 10^9/L)\), clozapine should be discontinued and the patient monitored closely. Granulocyte colony-stimulating factor filgrastim has been used in hope of hastening resolution or decreasing morbidity. In cases of moderate neutropenia (granulocytes 2,000–3,000/mm\(^3\) \([2 \times 10^9/L\) to \(3 \times 10^9/L]\), or ANC 1,000–1,500/mm\(^3\) \([1 \times 10^9/L\) to \(1.5 \times 10^9/L]\)), which occurs in up to 2% of patients, clozapine should be discontinued with daily monitoring of complete blood counts until values return to normal.

### Dermatologic System

Allergic reactions are rare and usually occur within 8 weeks of initiating therapy, manifesting as maculopapular, erythematous, pruritic rashes that are evident on the face, neck, trunk, or extremities. Contact dermatitis, including the oral mucosa, can occur in patients or medical personnel. For patients, mixing the antipsychotic concentrate in a sufficient quantity of a nonacidic liquid and swallowing it quickly decreases problems in susceptible patients. Care should be taken in the handling and preparation of liquid FGAs.

Phenothiazine can absorb ultraviolet light, resulting in the formation of free radicals, which can have damaging effects on the skin. Both SGAs and FGAs cause photosensitivity. Erythema and severe sunburns can occur. Exposure to sunlight should be limited, and patients should be educated about the use of a maximally blocking sunscreen, hats, protective clothing, and sunglasses.\textsuperscript{97,98}

Blue-gray or purplish skin coloration in areas exposed to sunlight occurs in patients receiving higher doses of low-potency phenothiazines during long-term administration, especially with chlorpromazine. It commonly occurs with concurrent corneal or lens pigmentations.

### Miscellaneous Adverse Effects

Toxicity with overdose

Acute overdose with antipsychotics rarely results in serious somatomatoid. Mild intoxication manifests as sedation, hypotension, and miosis, whereas with severe intoxication, agitation and delirium can typically progress to motor retardation, seizures, cardiac arrhythmias, respiratory arrest, and coma. Dystonias and pseudoparkinsonism symptoms also occur. Supportive measures, gastric lavage, and activated charcoal are recommended. Induction of emesis can be difficult because of effects on the chemoreceptor trigger zone, and dialysis is ineffective because of the degree of drug-protein binding. Phenytoin or sodium bicarbonate are useful in the treatment of quinidine-like cardiac conduction effects on the QRS or QTc. Phystostigmine is not generally recommended to reverse anticholinergic toxicity because of deleterious effects on arrhythmias and seizure threshold.\textsuperscript{98}

Use in pregnancy and lactation

Minimal data exist regarding the effects of pregnancy on schizophrenia. However, disorganized thought processes, impaired cognition, and negative symptoms can have a detrimental effect on the functioning and self-care of the mother, and therefore
adversely affect the fetus.¹⁰⁰ Currently available data assessing the risk of teratogenesis with antipsychotic agents are insufficient. Epidemiologic studies show a slightly increased risk of birth defects with low-potency FGAs. Haloperidol is the best studied of all antipsychotics, and no relationship between its use and teratogenicity has been found. A recent study has shown a greater than 2-fold elevated risk of preterm birth in women with schizophrenia taking FGAs as compared with unexposed mothers not taking antipsychotics.¹⁰¹

SGAs have increasing information available regarding safety in pregnancy; however, very few large studies and very few prospective studies have been performed to evaluate possible teratogenicity of SGAs. Definitive data are still lacking. Two prospectively designed nonrandomized, observational studies have reported no increased risk of teratogenic birth defects with SGA exposure.¹⁰²,¹⁰³ One large registry data study performed in Sweden found a significant increased risk of cardiovascular defects with FGA or SGA exposure;¹⁰⁴ however, when stratifying by antipsychotic class, it was found that all defects were found in those exposed to FGAs, while no cardiovascular defects were reported with SGAs.¹⁰⁵

Studies have shown differing results in regard to neonatal outcomes in infants exposed to SGAs in utero. Women with schizophrenia taking SGAs showed no significant risk of low birth weight (LBW), preterm birth, or infant considered small or large for gestational age (LGA) when compared to infants born to unaffected and unexposed mothers.¹⁰⁶ One prospectively designed study found a higher rate of LBW infants in mothers taking SGAs (10%) than in the reference group (2%),¹⁰⁷ while another recent prospective study reported higher rates of LGA infant births in women taking SGAs compared with those in the FGA and reference groups.¹⁰⁸

Other potential interests in studying early and late exposure to antipsychotics include postnatal and gestational complications. Concern has been expressed regarding the use of clozapine in pregnancy.¹⁰⁹ The weight gain associated with olanzapine and clozapine and potential risk of gestational diabetes¹¹⁰ should be considered in drug selection. Risk of neonatal EPS has been shown to be increased in those exposed in utero to FGAs, with effects in the infant lasting for 3 to 12 months after birth.¹¹¹ Other adverse neonatal outcomes reported in babies of mothers taking SGAs include respiratory complications and hypotonia.¹¹²

The risk of antipsychotic use must be weighed against the benefits of pharmacotherapy in pregnant women experiencing disorganized thoughts, delusions about change in body image or pregnancy, or who are unable to provide adequate prenatal care.¹¹³

Antipsychotics appear in breast milk with milk-to-plasma ratios of 0.5 to 1. However, 1 week after delivery, clozapine milk concentrations have been found to be as much as 279% of serum concentrations. Its use during breastfeeding is not recommended.¹¹⁴ Overall, little is known about breast-feeding and the potential effects of antipsychotics on the neonate. Although not contraindicated, the lowest dosage should be used in the mother, and the infant should be carefully monitored.

### DRUG INTERACTIONS

Most drug interactions occur because of pharmacodynamic or pharmacokinetic interactions. Common examples of pharmacodynamic interactions resulting in enhanced effect include the excess sedation that can occur when antipsychotics are used concomitantly with other medications that have sedative side effects. Additive antimuscarinic effects of antipsychotics used with other medications with antimuscarinic effects can result in urinary retention, constipation, blurred vision, or other anticholinergic side effects.⁰³,¹¹⁵ Both combined sedative and anticholinergic effects from multiple medications can result in impaired cognition, particularly in the elderly and other patients predisposed to such problems.¹¹⁶ Patients are more likely to experience symptomatic orthostatic hypotension when an antipsychotic is used with other medications that cause orthostasis. Although metoclopramide is prescribed for treating esophageal reflux, it is a DA antagonist, and patients are more likely to experience akathisia and other EPS if it is used concomitantly with antipsychotics.⁷² Although some SSRIs can interact with antipsychotics through enzyme inhibition, they can also interact through pharmacodynamic mechanisms. 5-HT₂ receptors are present on the presynaptic dopaminergic neuron, and their activation leads to decreased dopamine release from the presynaptic terminal. Increased availability of serotonin through SSRI effect can activate these receptors, decrease dopamine release, and add to the dopaminolytic effects of antipsychotics.⁷² In the absence of enzyme inhibition, SSRIs can still precipitate akathisia or EPS when added to a patient stabilized on an antipsychotic. A potentially more dangerous interaction can occur when medications that slow myocardial conduction and thus prolong the QTc, are used in combination with antipsychotics that significantly prolong the QTc.⁷³ Medications that prolong the QTc should be monitored carefully in patients taking concomitant diuretics.⁷² These effects can all increase the risk of clinically significant side effects.

Asenapine inhibits CYP2D6, and is the only SGA that has been shown to significantly affect the pharmacokinetics of other medications.⁷⁴ Table 76–6 lists the major pathways thought to be involved in the metabolism of SGAs. Risperidone is metabolized primarily by CYP2D6 to its active metabolite, 9-OH-risperidone (paliperidone), which is thought to have a similar pharmacodynamic profile.⁷² CYP1A2 is the primary isoenzyme for metabolism of asenapine with CYP3A4 also being a significant pathway.⁵⁰

Based on current information, inhibitors of CYP1A2 have the greatest potential for causing interactions with clozapine and olanzapine.¹⁰⁶ Examples include cimetidine, fluvoxamine, and fluoroquinolone antibiotics (e.g., ciprofloxacin) to varying degrees. To date, however, no serious inhibition interactions have been reported with olanzapine, which may be a result of olanzapine’s wide therapeutic index. Carbamazepine has been reported to increase olanzapine elimination by as much as 50%.¹¹⁷ Cigarette smoking is a potent inducer of CYP1A2, and one would expect lower mean olanzapine serum concentrations in smokers compared with nonsmokers.

Because of the risk of seizures with higher clozapine tissue concentrations, interactions which inhibit clozapine’s metabolism are potentially significant. In particular, fluvoxamine increases clozapine serum concentrations by an average of two- to three-fold and up to five-fold.¹¹⁸,¹¹⁹ Fluoxetine and erythromycin can increase clozapine serum concentrations in some patients but to a lesser degree.¹¹⁸,¹¹⁹ Mean clozapine serum concentrations are reported to be 32% lower in smokers compared with nonsmokers.¹¹⁸ Carbamazepine can induce clozapine metabolism and lead to lower serum concentrations.¹¹⁸

A study with the potent CYP3A4 inhibitor ketoconazole showed minimal effects on ziprasidone single-dose pharmacokinetics, with only a 33% mean increase in the ziprasidone area under the time-versus-concentration curve.² These results are consistent with data suggesting that aldehyde oxidase is the major metabolic pathway for ziprasidone, with only 30% to 35% being metabolized by CYP3A4.¹¹²

Modest elevations of aripiprazole serum concentration occur in the presence of ketoconazole or quinidine, which inhibit CYP2D6 and 3A4, respectively. Carbamazepine has been reported to decrease aripiprazole serum concentrations.¹³¹,¹¹¹ Since iloperidone is metabolized through CYP2D6 and 3A4, its clearance can be impaired by inhibitors of these pathways. Since iloperidone prolongs the QTc interval, these types
It is estimated that approximately 80% of individuals suffering their first schizophrenic break will have recurrent episodes and significant lifetime psychosocial dysfunction. In 2004, the direct cost of treating schizophrenia in the United States was estimated to be

nearly $23 billion and the total costs were over $62.6 billion.113 The public mental healthcare sector provides the majority of services for individuals with schizophrenia. Mental healthcare costs for schizophrenia represent disproportionate expenditures for crisis intervention and hospitalization as compared with comprehensive outpatient services oriented toward maintaining remission and improving psychosocial functioning. The suboptimal or inadequate funding provided for efficient ambulatory mental health services further increases the demand for hospitalization, which diverts revenues that might be available for outpatient services. This has created a vicious revolving door cycle and is a major challenge facing public mental healthcare.

The advent of more expensive SGAs, accompanied by limited resources, has forced mental healthcare organizations to examine the outcomes and related economics of treating patients with SGAs compared with traditional, largely generic FGAs. Although several retrospective database studies found total mental health-care cost advantages for SGAs versus FGAs, in the prospective
EVALUATION OF THERAPEUTIC OUTCOMES

Assessment of response has traditionally been done subjectively or empirically (a relative sense of how the clinician feels the patient is doing). A formal mental status examination (MSE) is used to structure the patient interview and focus on items related to appearance, mood, sensorium, intellectual functioning, and thought processes. However, the MSE is not specific for the measurement of drug response. Clinicians should be trained to use simple, standardized psychiatric rating scales to assist in objectively rating patient drug responses. The Brief Psychiatric Rating Scale (BPRS) and the Positive and Negative Symptom Scale (PANSS) were developed for use in clinical trials as research tools to quantify symptoms and improvement seen with antipsychotic treatment. Objectively, the use of a numeric indicator (e.g., 20%, 30%, or 40% reduction in BPRS score) has been used to quantify overall symptom reduction and classify patients according to different degrees of response. However, these types of rating scales are too long and unwieldy to be routinely used within the time constraints of most clinical practices. Symptom scales used in clinical practice must be sufficiently brief to be used during an ordinary clinic visit (e.g., 15–30 minutes) while measuring both positive and negative symptoms, and being sufficiently representative of overall symptomatology. The four-item Positive Symptom Rating Scale and the Brief Negative Symptom Assessment are brief scales that meet such criteria (Table 76–10). It is increasingly recognized that clinicians should be examining cognition as an outcome in treatment of schizophrenia. A brief cognition battery has been developed and validated, and it can be completed in 15 to 20 minutes.

Similarly, the pharmacotherapeutic plan should include specific monitoring parameters for side effects. The plan should include how the potential side effect will be evaluated, and the frequency of assessment. Given the risk of weight gain, diabetes, and lipid abnormalities associated with many of the SGAs, a consensus task force led by the American Diabetes Association recommends the following baseline parameters before beginning antipsychotics: family history, weight, height, body mass index, waist circumference, blood pressure, fasting plasma glucose, and fasting lipid profile. They also recommend follow-up monitoring of these parameters after beginning or changing SGAs. Weight should be monitored monthly for the first 3 months, and quarterly thereafter. The other parameters should be assessed at the end of 3 months and then annually. If normal, serum lipids can be monitored less often. Self-assessments can be a useful adjunct in treating the patient. Although the patient with schizophrenia may not always be accurate in evaluating symptom severity, the use of patient self-assessments increases patient engagement in care, enhances therapeutic alliance, and gives the clinician an opportunity to identify misconceptions the patient can have regarding symptoms associated with the illness, medication side effects, and the like. Traditionally, clinicians have often accepted partial symptom response in schizophrenia as success, and have not been aggressive in attempting to achieve greater symptomatic remission. The advent of multiple different SGAs with varying, but overall favorable, side-effect profiles should encourage clinicians to be more assertive in attempting to achieve symptom remission. This is consistent with an increasing focus on remission as a goal of treatment and evolving recovery movements with an emphasis on consumerism in the care of the severely mentally ill. A recent study showing how the Internet can be used to aid relapse prevention efforts gives us a glimpse of how consumerism may enhance and influence the care for schizophrenia in the future.

CONCLUSIONS

Schizophrenia is a complex disease with multiple ramifications for patients and their families. Treatment issues remain clouded by the fact that the etiology of the illness is unknown. It is clear that no single treatment modality is adequate to properly manage a patient with schizophrenia. Antipsychotics are the bedrock of treatment. Antipsychotics are not a panacea and have multiple adverse effects that limit their effectiveness. However, when used within the context of multidisciplinary treatment, antipsychotics improve symptoms so that patients can appropriately participate in psychosocial rehabilitation programs. Scientific advances continue to expand our understanding of CNS physiology and the abnormalities present in schizophrenia. Advances in our understanding of the pathophysiology of schizophrenia should, in turn, result in the development of treatments that are more specific and more effective. In practice, it is mandatory that clinicians appropriately use their expanding armamentarium. It is important that clinicians appreciate the pharmacodynamic basis for treatment interventions so that they can effectively design and implement rational pharmacotherapeutic regimens. Finally, it is critical that clinicians more objectively evaluate individual patient response to medication so that treatment can be optimized. With these strategies, the gap between practice and science can be narrowed and patients’ lives benefited.

KEY CONCEPTS

1. Extensive treatment guidelines are available to assist in the treatment of major depressive disorder, including medication management. Clinicians treating individuals with major depressive disorder should be familiar with these guidelines.

2. When evaluating a patient for the presence of depression, it is essential to rule out medical causes of depression and drug-induced depression.

3. The goal of pharmacological treatment of depression is the resolution of current symptoms (i.e., remission) and the prevention of further episodes of depression (i.e., relapse or recurrence).

4. When counseling patients with depression who are receiving antidepressant medications, the patient should be informed that adverse effects might occur immediately, while resolution of symptoms may take 2 to 4 weeks or longer. Adherence to the treatment plan is essential to a successful outcome, and tools to help increase medication adherence should be discussed with each patient.

5. Antidepressants are generally considered equally efficacious in groups of patients with major depressive disorder. Therefore, other factors, such as age, side effects, and past history of response, are used to guide the selection of medication management.

6. When determining if a patient has been nonresponsive to a particular pharmacotherapeutic intervention, it must be determined whether the patient has received an adequate dose for an adequate duration and whether the patient has been medication adherent.

7. When evaluating response to an antidepressant, in addition to target signs and symptoms, the clinician must consider quality-of-life issues such as role, social, and occupational functioning. In addition, the tolerability of the agent should be assessed because the occurrence of side effects may lead to medication nonadherence, especially given the chronicity of the disease and need for long-term medication management.

A diagnosis of major depressive disorder is given when an individual experiences one or more major depressive episodes without a history of manic, mixed, or hypomanic episodes. A major depressive episode is defined by the criteria listed in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR). Depression is associated with significant functional disability, morbidity, and mortality.

Newer generations of antidepressants have provided pharmacological interventions that are effective and better tolerated than older agents like the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs). In addition, substantial efforts have been undertaken to improve the ability of clinicians to recognize and appropriately treat the signs and symptoms of depression. This chapter focuses exclusively on the diagnosis and treatment of major depressive disorder.

In the absence of well-accepted evidence-based medicine for the medication management of major depressive disorder, the reader is referred to the Practice Guideline for the Treatment of Patients with Major Depressive Disorder, Second Edition, which is available at www.psych.org. This extensive document is a practical guide to the management of depression based upon the best available data as well as clinical consensus.

EPIDEMIOLOGY

The true prevalence of depressive disorders in the United States is unknown. The National Comorbidity Survey Replication found that 16.2% of the population studied had a history of major depressive disorder in their lifetime, and more than 6.6% had an episode within the past 12 months. Women are at increased risk of depression from early adolescence until their mid-50s, with a lifetime rate that is 1.7 to 2.7 times greater than for men. Although depression can occur at any age, adults 18 to 29 years of age experience the highest rates of major depression during any given year. The estimated lifetime prevalence of major depression in individuals aged 65 to 80 recently was reported to be 20.4% in women and 9.6% in men. Depressive disorders are common during adolescence, with comorbid substance abuse, suicide attempts, and deaths occurring frequently in these young patients. Depressive disorders and suicide tend to occur within families. For example, approximately 8% to 18% of patients with major depression have at least one first-degree relative (father, mother, brother, or sister) with a history of depression, compared with 5.6% of the first-degree relatives of those without depression. Furthermore, first-degree relatives of patients with depression are 1.5 to 3 times more likely to develop depression than normal controls. A recent meta-analysis found that the heritability of liability for major depression was 37%, whereas the remaining 63% of the variance in liability was due to individual-specific environment. Therefore major depressive disorder is relatively common, occurs

Antidepressants block the reuptake of neurotransmitters, which allows more neurotransmitters to remain in the synapse for later use or broken down by enzymes. For their primary mechanism of action, most antidepressants are thought to inhibit the transporter molecules and allow more NE to remain in the synapse. This figure was reproduced from the Mind Over Matter educational series, which is in the public domain and may be reproduced without permission. (Source: U.S. Department of Health and Human Services, National Institutes of Health, National Institute on Drug Abuse, Office of Science Policy and Communications, Science Policy Branch.)

ETIOLOGY

The etiology of depressive disorders is too complex to be totally explained by a single social, developmental, or biologic theory. Several factors appear to work together to cause or precipitate depressive disorders. The symptoms reported by patients with major depression consistently reflect changes in brain monoamine neurotransmitters, specifically norepinephrine (NE), serotonin (5-HT), and dopamine (DA). Please see Figure 77–1 for a visual explanation as to how these monoamine neurotransmitters are regulated at the level of the neuron and within the synapse.

PATHOPHYSIOLOGY

Several years before the introduction of antidepressants, the cause of depression was linked to decreased brain levels of the neurotransmitters NE, 5-HT, and DA, although the actual cause remains unknown. This biogenic amine hypothesis evolved as a result of several observations made in the early 1950s. It was noted that the antihypertensive drug reserpine depleted neuronal storage granules of NE, 5-HT, and DA and produced clinically significant depression in 15% or more of patients.

Although the reuptake blockade of monoamines (e.g., NE, DA, and 5-HT) occurs immediately upon administration of an antidepressant, the clinical antidepressant effects (i.e., measurable improvement) are generally delayed by weeks. This delay may be the result of a cascade of events from receptor occupancy to gene transcription. This delay in onset of action has caused researchers to focus on the adaptive changes induced by antidepressants. Accordingly, theories that focus on adaptive (or chronic) changes in amine receptor systems have emerged over the past decade. In the mid-1970s, it was recognized that chronic, but not acute, administration of antidepressants to animals caused desensitization of NE-stimulated cyclic adenosine monophosphate synthesis. In fact, for most antidepressants, downregulation of β-adrenergic receptors accompanies this desensitization. Studies of many antidepressants have demonstrated that either desensitization or downregulation of NE receptors corresponds to a clinically relevant time course for antidepressant effects. Other studies have revealed desensitization of pre-synaptic 5-HT1A autoreceptors following chronic administration of antidepressants. Thus a theory based on changes in receptor sensitivity provides a cogent explanation of the delayed onset of therapeutic response of antidepressant drugs. The dysregulation hypothesis incorporates the diversity of antidepressant activity with the adaptive changes occurring in receptor sensitization over several weeks. In this theory, emphasis is placed on a failure of homeostatic regulation of neurotransmitter systems rather than on absolute increases or decreases in their activities. According to this hypothesis, effective antidepressant agents restore efficient regulation to the dysregulated neurotransmitter system.

It is apparent that no single neurotransmitter theory of depression is adequate. The 5-HT/NE link hypothesis maintains that both the serotonergic and noradrenergic systems are involved in an antidepressant response. This hypothesis is also consistent with the rationale of the postsynaptic alteration theory of depression, which emphasizes the importance of β-adrenergic receptor downregulation for achieving an antidepressant effect. Furthermore, both serotonergic and noradrenergic medications down-regulate β-adrenergic receptors, and there is a link between serotonin and norepinephrine. This implies that medications that are effective in the treatment of depression act at both of these neurotransmitter systems.

Traditional explanations of the biologic basis of depressive disorders have focused largely on NE and 5-HT; however, most of the evidence that coalesced into the biogenic amine hypothesis of depression does not clearly distinguish between NE and DA. There is an abundance of evidence suggesting that dopamine transmission is decreased in depression and that agents that increase dopaminergic transmission have been found to be effective antidepressants. Specifically, studies suggest that increased DA transmission in the mesolimbic pathway account for at least part of the mechanism of action of antidepressant medications. The mechanisms by which antidepressant drugs alter DA transmission remain unclear, but may be mediated indirectly by primary actions at NE or 5-HT terminals. The complexity of the interaction between 5-HT, NE, and possibly DA is gaining greater appreciation, but a more in-depth understanding of the precise mechanism is needed.

More recent insight into the possible mechanisms underlying depressive disorders comes from studies on brain-derived neurotrophic factor (BDNF). BDNF is a growth factor protein that regulates the differentiation and survival of neurons. A growing body of evidence suggests this process might be disrupted in depressive disorders. More specifically, chronic stress and an associated increase in glucocorticoids such as cortisol may cause a disruption of BDNF expression in the hippocampus. This process may be prevented, or possibly even reversed, by antidepressant medications. This is a relatively recent theory, which has not been firmly established. However, if proven valid, it demonstrates that antidepressants may help prevent deleterious effects of chronic stress and depressive symptoms.

BIOLOGIC MARKERS

Investigators continue to search for biologic or pharmacodynamic markers to assist in the diagnosis and treatment of depressed
patients. Although no biologic marker has been discovered, several biologic abnormalities are present in many depressed patients. Approximately 45% to 60% of patients with major depression have a neuroendocrine abnormality, including hypersecretion of cortisol or a lack of cortisol suppression after dexamethasone administration (i.e., a positive dexamethasone suppression test). In fact, it has been suggested that the inability of the brain to suppress the hypothalamic-pituitary-adrenal (HPA) axis and the associated stress response could lead to the pathophysiology and symptoms of depression.\(^\text{22}\) According to this theory, there is a disruption somewhere in the normal negative feedback system that controls cortisol levels (please see Figure 85–3 in the Adrenal Gland Disorders chapter for a visual display of this negative feedback system). There are many potential negative consequences of excess circulating cortisol, including disruption in BDNF expression as discussed above in the Pathophysiology section.

Unfortunately, the high rate of false-positive and false-negative results associated with neuroendocrine abnormalities in depressed patients limits the usefulness of testing for these markers, and has led to their relative lack of use in clinical practice. However, they still provide a clue as to the potential pathophysiology of depressive disorders, which may lead us to more effective treatment options.

### DEPRESSION RATING SCALES

Instruments to assess the severity of depressive symptoms can be used for both clinical and research purposes. For example, the Montgomery-Åsberg Depression Rating Scale (MADRS) is a clinician-administered scale that is commonly used in drug trials given its sensitivity to change.\(^\text{25}\) Other depression rating scales are self-administered. For example, the Beck Depression Inventory (BDI) takes only 5 to 10 minutes to complete by the respondent.\(^\text{26}\) For a more detailed explanation for both of these instruments, as well as other rating scales and evaluation approaches, please refer to Chapter 71.

### EMOTIONAL SYMPTOMS

A major depressive episode is characterized by a persistent, diminished ability to experience pleasure. A loss of interest and pleasure in usual activities, hobbies, or work is common. Patients appear sad and electrolyte determinations to identify any potential medical problems. Lastly, a complete medication review should be performed because several medications may contribute to depressive symptoms (Table 77–1).\(^\text{24}\) Once a medical condition or concomitant medication has been ruled out as the cause of the depressive symptoms, the patient should be evaluated for a major depressive disorder.

According to the DSM-IV-TR, a single major depressive episode is characterized by five or more of the symptoms described in Table 77–2. At least one of the symptoms is depressed mood (often an irritable mood in children or adolescents) or loss of interest or pleasure in nearly all activities.\(^\text{1}\) These symptoms must have been present nearly every day for at least 2 weeks and must represent a change from the patient’s previous level of functioning. The clinician must consider presenting symptoms, their duration, and the patient’s current level of social, occupational, or other important areas of functioning. Significant stressors or life events may trigger depression in some individuals but not others; and there may be an important precipitant at the beginning of the disorder.\(^\text{1}\) A patient diagnosed with major depressive disorder may have one or more recurrent episodes of major depression during their lifetime.

DSM-IV-TR Criteria for Major Depressive Episode

<table>
<thead>
<tr>
<th>Table 77-2 DSM-IV-TR Criteria for Major Depressive Episode</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.</td>
</tr>
<tr>
<td>Note: Do not include symptoms that are clearly due to a general medical condition or mood-incongruent delusions or hallucinations.</td>
</tr>
</tbody>
</table>

1. Depressed mood most of the day, nearly every day
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day nearly every day
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day
4. Insomnia or hypersomnia nearly every day
5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
6. Fatigue or loss of energy nearly every day
7. Feelings of worthlessness or excessive or inappropriate guilt nearly every day
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

D. The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one), the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbidity preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

or depressed, and they are often pessimistic and believe that nothing will help them feel better. The presence of feelings of worthlessness or inappropriate guilt may identify patients at risk for suicide. Anxiety symptoms are present in almost 90% of depressed outpatients. Patients often have guilt feelings that are unrealistic, and these may reach delusional proportions. Patients may feel that they deserve punishment and may view their present illness as a punishment. A patient suffering from major depression with psychotic features may hear voices (auditory hallucinations) saying that he or she is a bad person and that he or she should commit suicide. Depression with psychotic features may require hospitalization, especially if the patient becomes a danger to self or others.

Physical symptoms often motivate patients, especially the elderly, to seek medical attention. Chronic fatigue is a common complaint, with a decreased ability to perform normal daily tasks. Fatigue often appears worse in the morning and does not improve with rest. Complaints of pain, especially headache, often accompany fatigue.

Sleep disturbances generally present as frequent early morning awakenings with difficulty returning to sleep. This may coexist with difficulty falling asleep and frequent nighttime awakening. Less frequently, depressed patients complain of increased sleep (hypersomnia), although they experience daytime exhaustion or fatigue.

Appetite disturbances, including complaints of decreased appetite, often result in substantial weight loss, especially in the elderly. Some patients lose 2 pounds (0.9 kg) or more per week without dieting. Other patients, especially in the ambulatory setting, may overeat and gain weight, although they actually may not enjoy eating. They may crave specific foods. Some patients exhibit gastrointestinal complaints, others cardiovascular complaints, especially palpitations. Patients frequently present with a loss of sexual interest or libido.

Intellectual or Cognitive Symptoms

Intellectual or cognitive symptoms include a decreased ability to concentrate, slowed thinking, and a poor memory for recent events. Patients may appear confused and indecisive. Depression should be considered when cognitive symptoms are present in the elderly.

Psychomotor Disturbances

Patients may appear noticeably slowed or retarded in physical movements, thought processes, and speech (psychomotor retardation). Conversely, depression may be accompanied by psychomotor agitation, manifesting as purposeless, restless motion (e.g., pacing, wringing of hands, or outbursts of shouting).

Suicide Risk Evaluation and Management

The Centers for Disease Control and Prevention lists suicide as the eleventh leading cause of death among Americans and the second leading cause of death among 25- to 34-year-olds. In 2006, there were 91 suicides per day in the United States. All patients diagnosed with major depression should be assessed for suicidal thoughts. Factors associated with an increased risk for suicide include psychiatric and substance use disorders, adolescence and younger age adults, physical illness, recent stressful life event, childhood trauma, hopelessness, and male gender. Those with a higher level of risk have high degrees of suicidal intent and describe more specific plans, in particular, those that are violent and irreversible. It is important to remember that the risk of suicide in those recovering from major depression may increase as they develop the energy and capacity to act on a plan made earlier in a course of illness. Additionally, despite factors to help identify those at greatest risk, it remains very difficult to predict suicidality in any given individual. Therefore, when suicidal intent is suspected, it is important to ask, “Are you thinking about harming or killing yourself?” If the risk is significant, the patient must be referred immediately to an appropriate healthcare professional. Additionally, certain depression rating scales, such as the MADRS discussed above, include questions that target suicidality, which may help identify those patients at risk.

In September 2004, the FDA required manufacturers of antidepressants to add a boxed warning stating that antidepressants increase the risk of suicidal thinking and behavior in short-term studies in children and adolescents with depressive disorders. These risks have become a new source of concern among those treating their patients with antidepressants. In order to help deal with the confusion these risks have caused, experts have recommended the following:

- It is especially important to closely monitor patients for suicidal ideation and behavior at the beginning of treatment and among younger patients.
- Discuss the possibility that adverse events may occur, including behavioral agitation or anger, and encourage patients to seek help should this occur.
- Deal with the subject of suicide directly.

It is important to note that there is little evidence to suggest that withholding antidepressant treatment decreases the risk of eventual suicide and may actually increase the risk. Furthermore, it may be that longer-term medication is needed for any protective effects against suicidality.

In May 2007, the FDA released additional requests to the makers of antidepressants that the black box warning regarding suicidality be expanded to include warnings about the increased risk of suicidality (thinking and behavior) in young adults 18 to 24 years of age, during the initial stages of treatment.

TREATMENT

**DESIRED OUTCOME**

The goals of treatment are to reduce the symptoms of acute depression, facilitate the patient’s return to a level of functioning like that before the onset of illness, and prevent further episodes of depression. Whether or not to hospitalize the patient is often the first decision that is made in consideration of the patient’s risk of suicide, physical state of health, social support system, and presence of a psychotic depression.

**GENERAL APPROACH TO TREATMENT**

1. There are three phases of treatment for patients with major depressive disorder: (1) the *acute* phase lasting from 6 to 10 weeks in which the goal is remission (i.e., absence of symptoms); (2) the *continuation* phase lasting 4 to 9 months after remission is achieved, in which the goal is to eliminate residual symptoms or prevent relapse (i.e., return of symptoms within 6 months of remission); and (3) the *maintenance* phase lasting at least 12 to 36 months in which the goal is to prevent recurrence (i.e., a separate episode of depression). The risk of recurrence increases as the number of past episodes increase. The duration of antidepressant therapy depends on the risk of recurrence. Some investigators recommend lifelong maintenance treatment for persons at greatest risk for recurrence (persons younger 40 years of age with two or more prior episodes and persons of any age with three or more prior episodes).

2. Educating the patient and their support system (e.g., family and friends) regarding the delay in antidepressant effects and the importance of adherence should occur before and during the entire course of treatment. The treatment of major depressive disorder generally includes nonpharmacologic and pharmacologic strategies, which are discussed in further detail below.

**NONPHARMACOLOGIC THERAPY**

In addition to pharmacologic interventions, psychotherapy should be employed whenever the patient is able and willing to participate. Psychotherapy alone is not recommended for the acute treatment of patients with severe and/or psychotic major depressive disorder. However, if the depressive episode is mild to moderate in severity, psychotherapy may be the first-line therapy. The effects of psychotherapy and antidepressant medications are considered to be additive. Combined treatment may be advantageous for patients with partial responses to either treatment alone and for those with a chronic course of illness. However, for uncomplicated, nonchronic major depressive disorder, combined treatment may provide no unique advantage. Although not extensively evaluated, cognitive therapy, behavioral therapy, and interpersonal psychotherapy appear equally effective. Maintenance psychotherapy as the sole treatment to prevent recurrence generally is not recommended. Often, medication alone may prevent a depressive recurrence during the maintenance phase.

Electroconvulsive therapy (ECT) is a safe and effective treatment for certain severe mental illnesses, including major depressive disorder as well as other selected psychiatric illnesses. Patients with depression are candidates for ECT when a rapid response is needed, risks of other treatments outweigh potential benefits, there is a history of poor response to antidepressants and a history of good response to ECT, and the patient expresses a preference for ECT. A course of ECT generally consists of either unilateral or bilateral ECT administered 2 to 3 times weekly for a total of 6 to 12 treatments. A rapid therapeutic response (10–14 days) has been reported. Although there are no absolute contraindications to the use of ECT, several conditions are associated with increased risk. These include increased intracranial pressure, cerebral lesions, recent myocardial infarction, recent intracerebral hemorrhage, bleeding, or otherwise unstable vascular condition. The use of an anesthetic as well as a nondepolarizing neuromuscular blocking agent decreases the morbidity associated with ECT. Adverse effects of ECT include cognitive dysfunction, cardiovascular dysfunction, prolonged apnea, treatment-emergent mania, headache, nausea, and muscle aches. Cognitive changes associated with ECT include confusion immediately after the seizure and retrograde and anterograde memory disturbance. Most cognitive disturbances are transient, but some patients may report permanent loss of memory for events occurring over the months before, after, or during treatment. Relapse rates during the year immediately following ECT are high unless maintenance antidepressant medication is prescribed. Guidelines developed by the American Psychiatric Association include indications and contraindications for the appropriate use of ECT, procedures for obtaining informed consent, and issues in administering ECT.

Another nonpharmacologic treatment for depression is bright light therapy. Bright light therapy consists of the patient gazing into a 10,000-lux intensity light box, which is slanted downward toward the patients face for approximately 30 minutes/day. It has shown effectiveness for treating both the winter “blues,” also known as seasonal affective disorder (SAD), and for adjunctive use in major depressive disorder with seasonal exacerbations. Light therapy is well tolerated, with minor visual complaints being the most frequently reported event. Consequently, anyone undergoing light therapy should receive baseline and periodic eye examinations. The combination of bright light therapy and an antidepressant may provide additional benefit beyond either approach alone.

**PHARMACOLOGIC THERAPY**

Antidepressants can be classified in several ways, including by chemical structure and the presumed mechanism of antidepressant activity. Although the link between the presumed mechanism of drug action and antidepressant response is tenuous, this classification has the advantage of being based on established pharmacology and clearly explains some of the common, but expected, adverse effects. The knowledgeable clinician can use these facts to tailor treatment to individual patient needs and thereby optimize treatment outcome. Currently available antidepressants and initial dosages are shown in Table 77–3.

Studies have found that antidepressants are of equivalent efficacy in groups of patients when administered in comparable doses. Because one cannot predict which antidepressant will be the most effective in an individual patient, the initial choice is made empirically. Factors that often influence the choice of an antidepressant include the patient’s history of response, pharmacogenetics (history of familial antidepressant response), patient’s concurrent medical history, presenting symptoms (e.g., fatigue as compared with psychomotor agitation), potential for drug–drug interactions, adverse events profile, patient preference, and drug cost. Although the pathophysiology of major depression remains elusive, the clinician can now select from multiple approved drug therapies with different mechanisms of action. Failure to respond to one antidepressant class or one antidepressant drug within a class...
does not predict a failed response to another drug class or another drug within the class. Approximately 65% to 70% of patients with varying types of depression improve with drug therapy, compared with 30% to 40% who are well documented to improve with placebo.

MIXED SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

Although TCAs are effective in treating all depressive subtypes, their use has diminished greatly due to the availability of equally effective therapies that are much safer in overdose and better tolerated. All TCAs potentiate the activity of NE and 5-HT by blocking their reuptake. However, the potency and selectivity of TCAs for the inhibition of reuptake of NE and 5-HT vary greatly among these agents (Table 77–4). Because TCAs affect other receptor systems including the cholinergic, neurologic, and cardiovascular systems, adverse events are reported frequently during TCA therapy.15

Venlafaxine inhibits 5-HT reuptake at low doses, and NE reuptake at higher doses; thus, it is referred to as a serotonin-norepinephrine reuptake inhibitor (SNRI). The primary active metabolite of venlafaxine (i.e., desvenlafaxine) is also an SNRI and has been approved to treat depressive disorders. Duloxetine is an SNRI with both 5-HT and NE reuptake inhibition across all doses. Some studies suggest that the SNRIs may be associated with higher rates of response and remission than other antidepressants; however, most of these studies involved venlafaxine, and not all studies support this conclusion.17

SEROTONIN SELECTIVE REUPTAKE INHIBITORS

The efficacy of serotonin selective reuptake inhibitors (SSRIs) is superior to placebo and comparable to other classes of antidepressants in treating patients with major depression.2,33 SSRIs are generally chosen as first-line antidepressants due to their safety in overdose and improved tolerability. Furthermore, the decision as to which SSRI to use within the class is typically based on the nuances of each medication, such as differences in drug interaction profile and other pharmacokinetic parameters (e.g., half-life), or due to cost considerations. These concepts will be discussed in greater detail later in this chapter.

TRIAZOLOPYRIDINES

Trazodone and nefazodone have dual actions on serotonergic neurons, acting as both 5-HT2 antagonists and 5-HT reuptake inhibitors. They may also enhance 5-HT1A-mediated neurotransmission.15 Trazodone blocks α1-adrenergic and histaminergic receptors leading to increased side effects (e.g., dizziness and sedation) that limit its use as an antidepressant. Recently, a longer-acting extended

release preparation of trazodone was approved by the FDA. However, its place in the treatment of major depressive disorder is yet to be determined. Nefazodone’s use as an antidepressant has declined as well after reports of hepatic toxicity began to emerge. The FDA-approved nefazodone labeling includes a black box warning describing rare cases of liver failure. The triazolopyridines are effective agents in treating major depression; however, they both carry risks that limit their usefulness as antidepressants.

■ AMINOKETONE

Bupropion has no appreciable effect on the reuptake of 5-HT, while having reuptake properties at both the norepinephrine and dopamine reuptake pumps. These pharmacological properties make bupropion unique among all currently available antidepressants.

■ TETRACYCLIC

Mirtazapine enhances central noradrenergic and serotonergic activity through the antagonism of central presynaptic α1-adrenergic autoreceptors and heteroreceptors. Furthermore, it antagonizes 5-HT1 and 5-HT2 receptors as well as histamine receptors. The antagonism of 5-HT1 and 5-HT2 receptors has been linked to lower anxiety and gastrointestinal side effects, respectively. Blockade of histamine receptors is associated with the sedative properties of mirtazapine.

■ MONOAMINE OXIDASE INHIBITORS

MAOIs increase the concentrations of NE, 5-HT, and DA within the neuronal synapse through inhibition of the MAO enzyme. Studies have demonstrated that similarly to TCAs, chronic therapy causes changes in receptor sensitivity (i.e., downregulation of β-adrenergic, α-adrenergic, and serotonergic receptors). The MAOIs phenelzine and tranylcypromine are nonselective inhibitors of MAO-A and MAO-B. Recently, a selegeline transdermal patch was approved by the FDA for treatment of major depressive disorder that allows inhibition of MAO-A and MAO-B in the brain, yet has reduced effects on MAO-A in the gut (see tyramine interactions with MAOIs below).

■ ST. JOHN’S WORT

Increasingly, consumers are choosing alternative forms of therapy, such as herbal medications including St. John’s wort. Evaluations have found mixed results regarding the efficacy of the active ingredient in St. John’s wort, hypericum, when compared with placebo and other antidepressants. St. John’s wort is available as an over-the-counter medication. Although this may allow certain advantages such as reduced cost of therapy and self-treatment, it also has the potential to result in circumvention of the healthcare system. St. John’s wort has been found to have significant drug interactions with commonly used medications. Perhaps most disconcerting is the fact that herbal

ADVERSE EFFECTS

Serotonin-Norepinephrine Reuptake Inhibitors

The adverse effects of antidepressant medications are summarized in Table 77–4. The TCAs affect several neurotransmitters and produce a wide range of pharmacologic actions, including several unwanted, but expected, adverse effects. The most commonly occurring side effects are dose-related and are associated with blockade of cholinergic receptors (anticholinergic effects) and include dry mouth, constipation, blurred vision, urinary retention, dizziness, tachycardia, memory impairment, and at higher doses, delirium. 41 Although some tolerance does develop to these adverse effects, they have the potential to impact patient adherence, particularly in the elderly and those receiving long-term maintenance therapy. Orthostatic hypotension is a common, dose-related, and potentially problematic adverse effect that has been attributed to the affinity of the TCAs for adrenergic receptors. 42 TCAs also cause cardiac conduction delays and may even induce heart block in patients with a preexisting conduction disorder. TCA overdose can produce severe arrhythmias. 43 Furthermore, the FDA released a warning in December 2009 that the desipramine prescribing information will be changed to reflect an increased risk of death in patients receiving desipramine who have a family history of sudden cardiac death, cardiac dysrhythmias, and cardiac conduction disturbances. More on this reaction can be found at the FDA’s MedWatch website. Therefore, caution should be exercised when prescribing these agents, especially in higher doses, to patients with clinically significant cardiac disease, and to patients with a family history of a cardiac event. Additional adverse effects that may lead to TCA nonadherence include weight gain and sexual dysfunction. 44 Abrupt withdrawal of TCAs is often associated with symptoms suggestive of cholinergic rebound (e.g., dizziness, nausea, diarrhea, insomnia, and restlessness), especially if the daily dose exceeds 300 mg. 45 Therefore, the dose should be tapered over at least several days.

The most commonly reported adverse effects with venlafaxine are similar to those of SSRIs and may be dose related; they include nausea, sexual dysfunction, and activation. 2 Venlafaxine may also cause a dose-related increase in diastolic blood pressure, and baseline blood pressure is not a useful predictor of the occurrence of this phenomenon. Blood pressure should be monitored regularly during venlafaxine therapy, and dosage reduction or discontinuation may be necessary if sustained hypertension occurs. 46 Duloxetine was relatively well tolerated in short-term clinical trials; however, experience with long-term studies and in a larger population of patients will more clearly define the risks and benefits of this newly approved antidepressant. The most commonly reported adverse events were nausea, dry mouth, constipation, decreased appetite, insomnia, and increased sweating. 37,48

Serotonin Selective Reuptake Inhibitors

The SSRIs include fluoxetine, citalopram, sertraline, paroxetine, escitalopram, and fluvoxamine. These drugs have a low affinity for histaminic, α,-adrenergic, and muscarinic receptors, and therefore they produce fewer anticholinergic and cardiovascular adverse effects than the TCAs, and are not usually associated with significant weight gain. 49,50,51 The most common adverse effects, which generally are mild and short lived, are gastrointestinal symptoms (i.e., nausea, vomiting, and diarrhea), sexual dysfunction in both males and females, headache, and insomnia. 52 A discontinuation or withdrawal syndrome may occur if SSRIs are abruptly discontinued. However, the longer the half-life of the drug and its active metabolite, the less likely a withdrawal syndrome will occur. 53,54 Although SSRIs are known to improve the anxiety symptoms associated with depression, a few patients experience an increase in anxiety symptoms or agitation early in treatment.

Triazolopyridines

Trazodone and nefazodone have minimal anticholinergic effects and 5-HT agonist side effects, but they can cause orthostatic hypotension. Sedation, cognitive slowing, and dizziness are the most frequent dose-limiting side effects associated with trazodone. 41 Common adverse effects associated with nefazodone include light-headedness, dizziness, orthostatic hypotension, somnolence, dry mouth, nausea, and asthenia (weakness). Due to the previously discussed potential for hepatic injury associated with nefazodone use treatment should not be initiated in individuals with active liver disease or with elevated baseline serum transaminases. 38 A rare but potentially serious adverse effect of trazodone is priapism, which is reported to occur in approximately 1 in 6,000 male patients. Some cases have required surgical intervention (1 in 23,000), and permanent impotence may result. 55 There have been no reports of priapism associated with nefazodone use in men, but there is a published case report of nefazodone-induced clitoral priapism. 56

Aminoketone

Adverse effects associated with bupropion include nausea, vomiting, tremor, insomnia, dry mouth, and skin reactions. The occurrence of seizures in patients taking bupropion appears to be strongly dose related, and may be increased by predisposing factors such as history of head trauma and CNS tumor. Additionally, bupropion use is contraindicated in patients with eating disorders such as bulimia and anorexia, as these patients are prone to electrolyte abnormalities and are therefore at higher risk for seizure activity. At daily doses of 450 mg (the FDA-approved maximum dose) or less, the incidence of seizures is 0.4%; 57,58 Due to its pharmacological profile (i.e., pro-adrenergic) bupropion may cause activation or agitation in some patients. 18

Tetracyclic

The most common adverse effects of mirtazapine are somnolence, weight gain, dry mouth, and constipation. Interestingly, side effects such as weight gain may be less with larger mirtazapine doses due to different mechanisms of action at different doses, 59 such as increased noradrenergic transmission as the dose is increased.

Monoamine Oxidase Inhibitors

The most common adverse effect of MAOIs is postural hypotension; this is more likely to occur with phenelzine than with tranylcypromine and may be minimized through divided dosage scheduling. Other common adverse effects include weight gain and sexual side effects (e.g., decreased libido, anorgasmia). 2 Phenelzine, the most frequently prescribed MAOI, has mild to moderate sedating effects, while tranylcypromine may exert a stimulating effect, and therefore insomnia can occur. In addition, fever, myoclonic jerking, and brisk deep tendon reflexes may occur. 56

Hypertensive crisis, a potentially serious and life-threatening but rare adverse reaction, may occur when MAOIs are taken concurrently with certain foods, especially those high in tyramine...
Education of patients taking MAOIs regarding dietary and medication restrictions is extremely important. Printed and verbal patient instructions should be provided. It is important that patients be instructed to consult a healthcare professional before taking any over-the-counter medications, including non-FDA approved items sold as herbal/dietary supplements. Patients should be taught to recognize the symptoms of hypertensive crisis and to seek immediate treatment should those symptoms occur.

**CLINICAL CONTROVERSY**

In recent years, numerous reports from the Food and Drug Administration warn healthcare providers of adverse effects associated with the use of the antidepressants in various populations. Many of these warnings have been accompanied by product labeling changes, including black box warnings. However, some of the warnings have not been unequivocally supported in the scientific literature. Therefore, the reader is encouraged to examine and understand these reports, and consider them within the context of the scientific literature.

### PHARMACOKINETICS

The pharmacokinetics of the antidepressants are summarized in Table 77–7. Bioavailability is low (30%–70% for most TCAs) as a result of the first-pass hepatic effect, which shows great interindividual variation. The TCAs have a large volume of distribution and concentrate in brain and cardiac tissue in laboratory animals. They are bound extensively and strongly to plasma albumin, erythrocytes, α, acid glycoprotein, and lipoprotein. The major metabolic pathways are demethylation, aromatic and aliphatic hydroxylation, and glucuronide conjugation. Enterohepatic cycling has been described. Metabolism of TCAs is linear within the usual dosage range. The elimination half-lives of the TCAs can vary greatly among individual patients.

Venlafaxine is metabolized to an active metabolite, O-desmethylenamafexine, which contributes to the overall pharmacological effect, and has received FDA approval as another option for the treatment of depressive disorders. Venlafaxine has the lowest plasma protein binding of any antidepressant (27%–30%), which reduces the likelihood of drug interactions via this mechanism. As might be expected, different formulations of venlafaxine with different pharmacokinetic profiles have lead to different adverse effect profiles. For example, venlafaxine extended-release, with its sustained plasma concentrations, has been associated with higher rates of sexual dysfunction among men (37%) as compared with the immediate-release formulation (6%).

The diversity of SSRIs is evident not only in their chemical structures, but also in their pharmacokinetic profiles. These unique pharmacokinetic attributes of each SSRI can be used to guide treatment. For example, the long half-life of fluoxetine and its active metabolite norfluoxetine may be beneficial in instances of partial nonadherence (e.g., missed doses). Conversely, caution must be taken to monitor for drug–drug interactions prior to combining another medication with fluoxetine. SSRIs are extensively distributed to the tissues, and all, with the possible exception of citalopram and sertraline, may have a nonlinear pattern of drug accumulation with long-term administration. Therefore, the relationship between the dose and observed effect (e.g., side effect) may change over time for the non-linear SSRIs, and this needs to be considered during treatment.

Bupropion is metabolized to multiple active metabolites (see Table 77–7). There are currently three formulations of bupropion (immediate release, sustained release, and extended release), which

are considered bioequivalent. The bupropion peak plasma concentrations are lower for the sustained-release formulation of bupropion, and it is believed this may contribute to a lower seizure risk with that formulation.

Mirtazapine undergoes extensive biotransformation to several metabolites and is primarily eliminated in the urine (renal elimination). However, these metabolites are present at such low plasma concentrations as to minimally contribute to the overall pharmacologic profile of mirtazapine.

Altered Pharmacokinetics

Factors that influence TCA plasma concentrations include disease states, genetics, age, cigarette smoking, and concurrent drug administration. Hepatic disease may result in increased TCA plasma concentrations. Renal failure does not alter nortriptyline metabolism, but the 10-hydroxy metabolite may accumulate, and protein binding may be diminished, with resulting enhanced sensitivity to the drug. Clinicians should be alert to the possibility of higher-than-expected plasma concentrations of some TCAs in the elderly.

In patients with cirrhosis, the half-lives of fluoxetine and norfluoxetine increased to 7.6 and 12 days, respectively. Patients with hepatic impairment had a twofold increase in plasma concentrations of paroxetine. Similarly, in patients with mild stable cirrhosis, the half-life of sertraline was 2.5 times greater than in patients without liver disease. Patients with renal impairment had a 2- to 4-fold increase in paroxetine plasma concentrations compared with normal volunteers. Plasma concentrations of SSRIs in the elderly are reported to be greater than in younger patients.

The clearance of venlafaxine, mirtazapine, and their metabolites may be reduced among patients with hepatic or renal disease, and doses should be adjusted accordingly. Elderly patients may require a dose reduction with mirtazapine.

Plasma Concentration and Clinical Response

Studies in acutely depressed patients have demonstrated a correlation between antidepressant effect and plasma concentrations for some TCAs. However, the patient’s clinical response, not plasma concentration, dictates dosage adjustments. Some patients with plasma concentrations outside the suggested therapeutic plasma concentration range respond, whereas others are nonresponsive regardless of their plasma concentration. See Table 77–3 for a listing of suggested therapeutic plasma concentration ranges. There are four TCAs (nortriptyline, desipramine, imipramine, and amitriptyline) with evidence to support an association between plasma concentrations and clinical response. However, the best established therapeutic range is for nortriptyline (50–150 ng/mL [190–570 nmol/L]), which appears to demonstrate a curvilinear plasma concentration-response relationship.

For the newer antidepressants, a correlation has not been established between plasma concentration and clinical response or adverse effects.

Plasma Concentration Monitoring

Because of interindividual variations in plasma concentrations achieved by a given dose, interpretation of plasma concentrations...
can be very difficult for the TCAs. Although plasma level monitoring is not performed routinely, some indications include inadequate response, relapse, serious or persistent adverse effects, use of higher-than-standard doses, suspected toxicity, elderly patients, pregnant patients, cardiac disease, suspected nonadherence, suspected pharmacokinetic drug interactions, and when the manufacturer of the product changes. If plasma concentration monitoring is used to detect nonadherence, a cut-off as low as 30 ng/ml for the TCAs has been suggested to avoid confusion with low bioavailability or unusually rapid metabolism. Plasma concentrations should be obtained at steady state, usually after a minimum of 1 week at constant dosage. Sampling should be performed during the drug elimination phase, usually in the morning, 12 hours after the last dose. Samples collected in this manner are comparable for patients on once-, twice-, or thrice-daily regimens.

### DRUG INTERACTIONS

#### Serotonin-Norepinephrine Reuptake Inhibitors

Because the TCAs are metabolized in the liver through the cytochrome P450 system, they may interact with other drugs that modify hepatic enzyme activity or hepatic blood flow. TCAs are also extensively protein bound, which can cause drug interactions through displacement from protein-binding sites. Many commonly used medications can interact when given concurrently with TCAs. Due to their frequent co-administration, a common drug interaction occurs between the TCAs and certain SSRIs, such as paroxetine and fluoxetine. These drugs are known to inhibit cytochrome P450 (e.g., CYP 2D6) with the resultant increase in TCA plasma concentrations. Although MAOIs and TCAs may be coadministered safely in refractory patients with apparent increased efficacy compared with monotherapy, severe reactions (e.g., hypertensive crisis) and fatalities have occurred. Therefore, this combination should be monitored extremely carefully. Lastly, the TCAs, SNRIs, and SSRIs can potentially be involved in a pharmacodynamic drug interaction known as the serotonin syndrome (SS). This phenomenon will be described in further detail for SSRI drug interactions (i.e., the medications most commonly associated with this reaction) and within Table 77–8, which summarizes drug interactions for the newer-generation antidepressants.

#### Serotonin Selective Reuptake Inhibitors

Drug–drug interactions may occur when an SSRI is coadministered with another drug metabolized through the cytochrome P450 system. Two of the isoenzymes of the cytochrome P450 system, 2D6 and 3A4, are responsible for the metabolism of more than 80% of currently marketed drugs. The ability of an SSRI, or any antidepressant, to inhibit or induce the activity of these enzymes will be a significant contributory factor in determining its capability to cause a pharmacokinetic drug interaction when administered concomitantly. Table 77–9 shows the cytochrome P450 enzyme inhibitory potential of the second- and third-generation antidepressant agents. In patients receiving a stable dose of any medication known to interact with SSRIs, if an SSRI is to be initiated, the starting dose should be low and titrated carefully to evaluate the potential importance of the interaction.

Certain pharmacodynamic drug interactions that may occur with SSRIs are concerning and require close monitoring. For example, the combination of an SSRI with another drug that augments serotonergic function (e.g., linezolid) can lead to SS, which is characterized by symptoms such as clonus, hyperthermia, and mental status changes. However, these symptoms are not unanimously agreed upon (please see Clinical Controversy below for additional information). Therefore, a washout period of 2 to 5 weeks (depending on the half-life of the SSRI) may be necessary before the initiation of another serotonergic medication.

### SPECIAL POPULATIONS

#### Elderly Patients

Depression in the elderly is a major public health problem. Many elderly depressed patients are inadequately treated, or depression is missed or mistaken for another disorder, such as dementia. In the elderly, depressed mood, the typical signature symptom of depression, may be less prominent than other depressive symptoms such as loss of appetite, cognitive impairment, sleeplessness, anergia, and loss of interest in and enjoyment of the normal pursuits of life. Older adults may not recognize common symptoms associated with depression such as anhedonia (inability to experience pleasure), fatigue, and concentration difficulties. Somatic (physical) complaints are quite frequently the presenting symptoms in elderly depressed patients. Appropriate recognition and treatment of depression in the elderly is extremely important. In fact, individuals 65 years of age and older have a very high rate of suicidality.

Data from references 49, 63, 70, and 71.

Pregnant and Lactating Patients
Approximately 14% of pregnant women develop a serious depression during pregnancy. The data presented in several recent publications should be considered when making treatment decisions for pregnant women suffering from major depression. The first evaluation looked at the risk of discontinuing antidepressant therapy in pregnant women suffering from depression and found a significant risk of relapse. In this study, women who discontinued antidepressant therapy were 5 times more likely to have a relapse during their pregnancy than were women who continued treatment. Another study utilized population health data to determine whether exposure to SSRIs and depression in pregnant women differs from exposure to maternal depression alone. The authors found that prenatal exposure to SSRIs was associated with an increased risk of low birth weight and respiratory distress, and that this relationship remained after accounting for maternal illness severity. A study by Chambers and colleagues reported a 6-fold greater likelihood of the occurrence of persistent pulmonary hypertension of newborn infants exposed to an SSRI after the 20th week of gestation. A recent editorial on the use of antidepressants in pregnancy lists four therapeutic principles to guide the clinician in treating women during pregnancy: (1) Pregnancy does not protect against the occurrence of depression, and the likelihood of relapse is very high in untreated women with recurrent illness. (2) Maternal depression adversely affects child development, and prenatal depression may adversely affect the offspring. (3) When attempting to balance benefit and risk, transient postnatal behavioral abnormalities in the offspring of treated mothers must not be assumed to portend long-term compromise. (4) SSRIs, the most commonly used and best-tolerated treatment for depression, carry a small but significant risk for a serious medical consequence.

In September 2009, the American Psychiatric Association and the American College of Obstetricians and Gynecologists released a report discussing the treatment of depression during pregnancy. One of the prominent conclusions of this report was that both antidepressant treatment and untreated depression have been associated with potential problems during pregnancy. However, studies to date have not been able to adequately control for all the necessary variables involved in birth outcomes (e.g., maternal depressive disorder) and more work needs to be done.

In summary, the risks and benefits of drug therapy during pregnancy must always be weighed, and concerns about the risks of untreated depression during pregnancy should be considered. These include the possibility of low-birth-weight secondary to poor maternal weight gain, suicidality, potential for hospitalization,
potential for marital discord, inability to engage in appropriate obstetric care, and difficulty caring for other children.\textsuperscript{91} Several different approaches exist for dealing with pregnancy and antidepressant use. First, discontinuation of an antidepressant before conception is an option for women who are stable and appear likely to remain well while not taking antidepressant medication. Second, continuation of the antidepressant until conception may be reasonable. For those who have a history of depressive relapse after medication discontinuation, the antidepressant should be continued throughout pregnancy. Further evaluations of the newer antidepressant agents are needed to fully understand the risks associated with their use at various stages of the gestational period. Again, the risks of not treating depression in a pregnant woman should not be underestimated or minimized.

There is a great deal of uncertainty regarding long-term antidepressant exposure during breastfeeding due to the lack of data. However, sertraline and paroxetine both appear in relatively low concentrations in breast milk and in samples taken from infants.\textsuperscript{92}

### Relative Resistance and Treatment-Resistant Depression

The majority of “treatment-resistant” depressed patients are likely the result of inadequate therapy (relative resistance). This theory is supported by data from the National Institute of Mental Health (NIMH) Sequenced Treatment Alternatives to Relieve Depression (STAR\textsuperscript{D}) study, which is generally considered to be one of the premier antidepressant trials among patients with depressive disorders.\textsuperscript{93} This study showed that one in three depressed patients who previously did not achieve remission using an antidepressant became symptom free with the help of an additional medication (e.g., an atypical antipsychotic to receive FDA approval for adjunctive antidepressant response. In fact, aripiprazole was the first atypical antipsychotic to receive FDA approval for adjunctive use in adults with major depressive disorder, and others will likely follow. Additionally, olanzapine \textit{in combination} with fluoxetine (Symbax) was approved for treatment resistant depression. Please refer to the FDA website for additional information on FDA approvals.

The American Psychiatric Association practice guideline for the treatment of patients with major depressive disorder offers guidance for managing patients who fail to respond. These guidelines advise that if patients fail to respond to medication after 6 to 8 weeks, a reappraisal of the treatment regimen should be considered.\textsuperscript{94} Partial responders should consider changing the dose, augmenting the antidepressant, or adding psychotherapy or ECT. For those with no response, options include changing to a second antidepressant or the addition of psychotherapy or ECT. Comorbid medical or psychiatric conditions should be identified and treated because they may complicate treatment. Before changing a patient’s treatment, the clinician is advised to evaluate the adequacy of the medication dosage and adherence with the prescribed regimen. A combination of two drugs should not be used when one drug will suffice.

**Issues to be addressed in assessing the patient who has not responded to treatment include the following:**

1. Is the diagnosis correct?
2. Does the patient have a psychotic depression?
3. Has the patient received an adequate dose and adequate duration of treatment?
4. Do adverse effects preclude adequate dosing?
5. Has the patient adhered to the prescribed regimen?
6. Was a stepwise approach to treatment used?
7. Was treatment outcome adequately measured?
8. Is there a coexisting or preexisting medical or psychiatric disorder?
9. Are there other factors that interfere with treatment?

### CLINICAL APPLICATION

A suggested algorithm for the management of uncomplicated major depressive disorder is shown in Figure 77–2. Recommended initial doses and dosage ranges are shown in Table 77–3. In elderly patients, as a general rule, dosing is initiated at one-half the initial dose administered to younger adults, and the dose is increased at a slower rate. The usual initial adult dose of most TCAIs is 25 mg at bedtime, and the dose may be increased by 25 to 50 mg every third day. The usual starting dose of venlafaxine is 75 mg/day and taken with food. Some patients may better tolerate a starting dose of 37.5 mg/day for a few days before beginning 75 mg/day. Depending on tolerability, the dose is then titrated to 150 mg/day. If needed, the dose may be further increased to 225 mg/day. Severely depressed patients may require doses as high as 375 mg/day. Both an immediate-release and extended-release formulation of venlafaxine are now available. Desvenlafaxine can be started and maintained at the same 50 mg dose, which may be an advantage compared with other antidepressants that need to be titrated up over time. Duloxetine can be started at 60 mg/day and titrated upward to 120 mg/day, given as a divided or single daily dose.

The recommended initial dose for the SSRIs citalopram, fluoxetine, and paroxetine is 20 mg and 10 mg for escitalopram. The initial dose for fluvoxamine and sertraline is 50 mg/day. The doses are titrated upwards depending on symptom response and adverse effects.

Bupropion is usually initiated at 75 mg twice daily, and this dose may be increased to 100 mg 3 times daily after a few days. Most patients will respond at 300 mg/day; however, an increase to...
Uncomplicated, physically healthy outpatient without any contraindication to a specific class of antidepressants

SSRI (choice depends on multiple factors)

Failed trial due to nonresponse or limiting adverse effect

Ensure medication adherence

Switch to alternative agent (different SSRI, non-SSRI antidepressant)

Failed trial

Partial response (after maximizing dose)

Consider augmentation (non-SSRI antidepressant, lithium, thyroid hormone, atypical antipsychotic)

Switch to alternative agent (different SSRI or non-SSRI antidepressant)

Failed trial

Partial response (after maximizing dose)

Response/remission

Maintain for at least 4 to 9 months for continuation, and if necessary, 12 to 36 months for maintenance

Response/remission

FIGURE 77-2. Algorithm for treatment of uncomplicated major depressive disorder. (SSRI, serotonin selective reuptake inhibitor.)

450 mg/day, given as 150 mg 3 times daily, may be considered in patients with no or partial response after several weeks of treatment at 300 mg/day. Additionally, both a 12-hour and 24-hour sustained-release formulation are available, allowing for less frequent dosing. The recommended starting dose of mirtazapine is 15 mg/day administered in a single dose at bedtime and the maximum recommended dose is 45 mg/day.

Caution is urged when switching from one antidepressant to another. It is important to remember that 3 to 4 weeks is usually required before a mood-elevating response is seen. A 6-week trial at a maximum dosage is considered an adequate trial. It is crucial to counsel the patient about the expected lag time before the onset of clinical response. Patients uneducated in this regard often fail to adhere to their prescribed regimens.

PHARMACOECONOMIC CONSIDERATIONS

Cost of illness studies attempt to provide an estimation of the amount spent on a particular disease and to identify different components of the cost. Ideally, direct, indirect, and intangible costs would be included. Direct costs include medical and nonmedical costs such as outpatient costs, inpatient costs, medication costs, transportation costs, and social services costs. Indirect costs include loss of productivity or reduced productivity. Intangible costs result from a decreased quality of life for the depressed individual and his/her family. Intangible costs are often not considered in pharmaco-economic models because an accurate quantification in monetary terms is difficult. Most published studies do not include all of the relevant aspects necessary for credible economic analyses. In addition, there is wide variability among studies with regard to cost inclusion and evaluation of treatment withdrawals, relapses, toxicity, and adverse effects. When SSRIs were introduced, many managed care organizations restricted these medications to those who had failed treatment with the TCAs or who had been unable to tolerate these agents, with the belief that the SSRIs represented a more expensive approach to the treatment of depression. One of the major claims for SSRIs is the greater tolerability and safety profile in overdose when compared with TCAs. All of the randomized clinical trials evaluating total expenditure of SSRIs versus TCAs indicate a cost-advantage associated with SSRIs. This advantage may be due to greater tolerability. Recently, several of the SSRIs have lost patent exclusivity, and generic versions of these medications are available at substantially lower prices than the brand name versions. Due to this generic availability, the restrictions placed on SSRIs have been removed from most, if not all, organizations.
Many of the new compounds, such as the SNRIs, are still restricted to second-line therapy or carry additional copay for the patient. This is likely to remain the case unless additional longer-term studies in more diverse populations are conducted that show an overall cost advantage for the newer agents. It would be extremely useful if cost-effective agents in various subpopulations and special populations (e.g., the elderly, those with comorbid substance abuse, those with comorbid anxiety disorders, and children) were identified. Also, the pharmacoconomics of medication management in various healthcare environments such as public, private, psychiatry, or primary care, needs further exploration. Pharmacoeconomic studies conducted to date are difficult to generalize, as there are no widely accepted uniform criteria, and studies vary greatly in accounting for factors such as adherence, treatment withdrawals, relapses, toxicity, and adverse effects. There is also great variability in the type of costs included.66

**EVALUATION OF THERAPEUTIC OUTCOMES**

Several monitoring parameters, in addition to plasma concentrations, are useful in managing patients. Patients must be monitored for adverse effects, such as sedation, anticholinergic effects, and for remission of previously documented target symptoms. The presence of side effects does not necessarily indicate adequate dosage. In addition, changes in social and occupational functioning should be assessed. Patients receiving venlafaxine should have their blood pressure monitored at regular intervals. Patients older than 40 years of age should receive a pretreatment ECG before starting TCA therapy, and follow-up ECGs should be performed periodically. Patients should be monitored for the emergence of suicidal ideation after initiation of any antidepressant. Weight gain and sexual dysfunction, common events associated with most antidepressants, are associated with nonadherence and should be monitored and discussed with the patient.

In addition to the clinical interview, psychometric rating instruments (such as those highlighted earlier in this chapter and in Chapter 71) allow for rapid and reliable measurement of the nature and severity of depressive and associated symptoms. It is helpful to administer the rating scales prior to treatment, 6 to 8 weeks after initiation of therapy, and periodically thereafter. Interviewing a family member or friend (with the patient’s permission) regarding symptoms and daily functioning also can assist in assessment of progress. Patients should be monitored at more frequent intervals early in treatment. Monitoring is then continued at regular intervals throughout the continuation and maintenance phases of treatment. Regular monitoring for reemergence of target symptoms should be continued for several months after antidepressant therapy is discontinued.

Finally, one useful set of criteria that can be used with a variety of psychometric scales was suggested by Mann.33 Following these criteria, the following definitions are used: (1) nonresponse is less than 25% decrease in baseline symptoms, (2) partial response is a 26%–49% decrease in baseline symptoms, and (3) partial remission or response is greater than a 50% decrease in baseline symptoms. Consistent with other recommendations, remission is a return to baseline functioning with no symptoms present.7

**COLLABORATIVE PRACTICE**

Significant evidence exists to show that depression is common, chronic, and causes significant morbidity and mortality. Pharmacists, in conjunction with other healthcare providers, can play a crucial role in the screening, recognition, and treatment of this disorder. In fact, the U.S. Preventive Services Task Force recommends screening adults for depression in clinical practices that have systems in place to ensure accurate diagnosis, effective treatment, and follow-up.100 In addition, pharmacists and other healthcare clinicians play a crucial role in ensuring adherence to medication regimens through assessment of a patient’s willingness and ability to take a medication, including an assessment of financial viability, and through patient education regarding dosing, side effects and drug interactions, and guidance regarding follow-up appointments with prescribing clinicians.101

**CONCLUSIONS**

Major depressive disorder remains one of the most commonly occurring mental illnesses in adults, and it is often undiagnosed and untreated. Pharmacologic intervention is the cornerstone of treatment for major depressive disorder. Antidepressant medications have a broad spectrum of neurochemical effects and influence a variety of receptors peripherally and centrally. Safe and effective use of antidepressants requires a thorough understanding of the pharmacology of these drugs and of the principles of treatment monitoring. Clinicians must have a thorough understanding of antidepressant drug interactions and factors that may influence their pharmacokinetic parameters. Lastly, safe and effective use of antidepressants depends on patient adherence to the prescribed antidepressant regimen. Pharmacists are in an ideal position to accomplish all of these treatment goals and promote the appropriate medication management of major depressive disorder.

**REFERENCES**

KEY CONCEPTS

1. Bipolar disorder is a cyclic mental illness with recurrent mood episodes that occur over a person’s lifetime. The symptoms, course, severity, and response to treatment differ among individuals.

2. Bipolar disorder is likely caused by genetic factors, environmental triggers, and the dysregulation of neurotransmitters, neurohormones, and second messenger systems in the brain.

3. The goal of therapy for bipolar disorder should be to improve functioning of the patient by reducing mood episodes. This is accomplished by maximizing the adherence to therapy and limiting adverse effects.

4. Patients and family members should be educated about bipolar disorder and treatments. Long-term monitoring and adherence to treatment are major factors in obtaining stabilization of the disorder.

5. Lithium and valproate are the mainstays of treatment for both acute mania and prophylaxis for recurrent manic and depressive episodes. Anticonvulsants, such as lamotrigine, carbamazepine, and oxcarbazepine, and second-generation antipsychotics, such as aripiprazole, olanzapine, risperidone, quetiapine, and ziprasidone are alternative or adjunctive treatments for bipolar disorder. Anticonvulsants may be more effective than lithium in several mood subtypes (e.g., mixed states and rapid cycling). The use of lithium, valproate, or quetiapine for acute bipolar depression should be considered as first-line treatment options.

6. Baseline and follow-up laboratory tests are required for some medications to monitor for adverse effects.

7. Some patients can be stabilized on one mood stabilizer, but others may require combination therapies or adjunctive agents during an acute mood episode. If possible, adjunctive agents should be tapered and discontinued when the acute mood episode remits and the patient is stabilized. Adjunctive agents may include benzodiazepines, additional mood stabilizers or antipsychotics, and/or antidepressants.

EPIEDEMOLOGY

The lifetime prevalence of bipolar I disorder (one or more manic or mixed episodes) is 0.4% to 1.6%; that for bipolar II disorder (recurrent major depressive episodes with hypomanic episodes) is approximately 0.5%. A national comorbidity survey reported that the lifetime prevalence rate of a manic episode is 1.6% ± 0.3% for men and 1.7% ± 0.3% for women in the United States (~4 million people). Bipolar I disorder occurs equally in men and women, whereas bipolar II disorder is more common in women.

ETIOLOGY

2. The exact etiology of bipolar disorder is unknown. Bipolar disorder is thought to be a complex genetic disease that is environmentally influenced and caused by a wide range of neurobiologic abnormalities. Stressful life events, alcohol or substance use, and changes in the sleep-wake cycle can elicit the expression of genetic or biologic vulnerabilities that cause dysregulation of neurotransmitters, neuroendocrine pathways, and second messenger systems. Table 78–1 summarizes the etiologic theories of bipolar disorder.

PATHOPHYSIOLOGY

2. Many theories have been proposed regarding the pathophysiology of mood disorders. Family, twin, and adoption studies report an increased lifetime prevalence risk of having mood disorders among first-degree relatives of patients with bipolar disorder. Genetic linkage studies suggest multiple gene loci can be involved in the heredity of mood disorders. Neuroimaging studies have found neurochemical, anatomic, and functional abnormalities in bipolar patients. Environmental or psychosocial stressors, nutritional deficiencies, infections, immunologic reactions, sleep deprivation, and disruption of circadian rhythms can cause dysregulation in neurotransmitters, hormones, endocrine function, neuropeptides, cations, intracellular second messengers, and signal transduction pathways.
SECTION 7
Psychiatric Disorders

Table 78-1  Etiologic Theories of Bipolar Disorder

<table>
<thead>
<tr>
<th>Genetic factors</th>
<th>80%–90% of patients with bipolar disorder have a biologic relative with a mood disorder (e.g., bipolar disorder, major depression, cyclothymia, or dysthymia). First-degree relatives of bipolar patients have a 15%–35% lifetime risk of developing any mood disorder and a 5%–10% lifetime risk for developing bipolar disorder. The concordance rate of mood disorders is 60%–80% for monozygotic twins and 14%–20% for dizygotic twins. Linkage studies suggest that certain loci on genes and the X chromosome may contribute to genetic susceptibility of bipolar disorder.</th>
</tr>
</thead>
</table>
| Nongenetic factors | Perinatal insult
Head trauma
Environmental factors
Desynchronization of circadian or seasonal rhythms cause diurnal variations in mood and sleep patterns and can result in seasonal recurrences of mood episodes. Changes in the sleep-wake cycle or light-dark cycle can precipitate episodes of mania or depression. Bright light therapy can be used for the treatment of winter depression and can precipitate hypomania, mania, or mixed episodes. Psychosocial or physical stressors
Stressful life events often precede mood episodes and can increase recurrence rates and prolong time to recovery from mood episodes. Nutritional factors
Deficiency of essential amino acid precursors in the diet can cause a dysregulation of neurotransmitter activity (e.g., L-tryptophan deficiency causes a decrease in 5-HT and melatonin synthesis and activity). Deficiency in essential fatty acids (e.g., omega-3 fatty acids) can cause a dysregulation of neurotransmitter activity. Neurotransmitter/neuroendocrine/hormonal theories
Dysregulation between excitatory and inhibitory neurotransmitter systems; excitatory: NE, DA, glutamate, and aspartate; inhibitory: 5-HT and GABA. Monoamine hypothesis
An excess of catecholamines (primarily NE and DA) cause mania. Agents that decrease catecholamines are used for the treatment of mania (e.g., DA antagonists and α-adrenergic agonists). Deficit of neurotransmitters (primarily NE, DA, and/or 5-HT) cause depression. Agents that increase neurotransmitter activity are used for the treatment of depression (e.g., 5-HT and NE/DA reuptake inhibitors and MAOIs). Dysregulation of amino acid neurotransmitters
Deficiency of GABA or excessive glutamate activity causes dysregulation of neurotransmitters (e.g., increased DA and NE activity). Agents that increase GABA activity or decrease glutamate activity are used for the treatment of mania and for mood stabilization (e.g., benzodiazepines, lamotrigine, lithium, or valproic acid). Cholinergic hypothesis
Deficiency of acetylcholine causes an imbalance in cholinergic-adrenergic activity and can increase the risk of manic episodes. Agents that increase acetylcholine activity can decrease manic symptoms (e.g., use of cholinesterase inhibitors or augmentation of muscarinic cholinergic activity). Increased central acetylcholine levels can increase the risk of depressive episodes. Agents that decrease acetylcholine activity can alleviate depressive symptoms (i.e., anticholinergic agents). Secondary messenger system dysregulation
Hyperthyroidism can precipitate manic-like symptoms. Hypothyroidism can precipitate a depression and be a risk factor for rapid cycling; thyroid supplementation can be used for refractory rapid cycling and augmentation of antidepressants in unipolar depression. Positive antithyroid antibody titers reported in patients with bipolar disorder. Hormonal changes during the female life cycle can cause dysregulation of neurotransmitters (e.g., premenstrual, postpartum, and perimenopause). Membrane and cation theories
Abnormal neuronal calcium and sodium activity and homeostasis cause neurotransmitter dysregulation. Hypocalcemia has been associated with causing anxiety, mood irritability, mania, psychosis, and delirium. Hypercalcemia has been associated with causing depression, stupor, and coma. Extracellular and intracellular calcium concentrations may affect the synthesis and release of NE, DA, and 5-HT, as well as the excitability of neuronal firing. Sensitization and kindling theories
Recurrences of mood episodes cause behavioral sensitivity and electrophysiologic kindling (similar to the amygdala-kindling models for seizures in animals) and can result in rapid or continuous mood cycling. |
affective state that is expressed is determined secondarily by the level of norepinephrine (NE) (e.g., increased amounts of NE lead to mania, decreased amounts lead to depression). L-tryptophan or 5-HT deficiency and changes in the light-dark cycle may result in reduced melatonin secretion from the pineal gland that disrupts the sleep-wake cycle, alters circadian rhythms, and causes seasonal affective changes.10,20

The catecholamine hypothesis of mood disorders suggests that increased DA and NE activity contribute to hyperactivity and psychosis associated with the severe stages of mania, and reduced DA and NE activity causes depression.3,10 A γ-aminobutyric acid (GABA) deficiency theory has been proposed for mania as it inhibits NE and DA activity.3,10,12 Glutamate and aspartate, excitatory amino acid neurotransmitters, may be overactive and involved in causing manic episodes.12 Cholinergic underactivity has been proposed to cause mania and overactivity of acetylcholine to cause depression.10,12 Acetylcholine is an antagonist of the catecholamine system and contributes to the interaction between phosphatidylinositol and phosphatidylcholine secondary messenger systems.12

DIAGNOSTIC DIFFICULTY

Several medical, medication-induced, or substance-related causes of mania and depression have been identified (see Table 78–2 for causes of mania and Table 77–1 in Chapter 77 for causes of depression).1,2 A complete medical, psychiatric, and medication history; physical examination; and laboratory testing are necessary to rule out any organic causes of mania or depression.2 An accurate diagnosis is important because some psychiatric and neurologic disorders present with manic-like or depressive-like symptoms.2,3 For example, attention-deficit/hyperactivity disorder and a manic episode have similar characteristics; thus, individuals with bipolar disorder can be misdiagnosed and prescribed central nervous system stimulants.3,21 Use of any substance that affects the central nervous system (e.g., alcohol, antidepressants, caffeine, central nervous system stimulants, hallucinogens, or marijuana) can worsen symptoms of mania or depression and decrease response to treatment.2,10,22–24

Another disease state that has a similar presentation to bipolar disorder is schizoaffective disorder. This disease is a mix between schizophrenia and bipolar disorder. Patients with schizoaffective disorder have mood episodes, but the distinguishing factor from bipolar disorder is that these patients experience psychosis even between mood episodes during periods of euthymia. Clinicians must rely on family members or others who know the patient well to determine if the patient is psychotic between mood episodes. It can be difficult for clinicians to obtain a full psychiatric history on patients, thus making schizoaffective disorder widely diagnosed. Schizoaffective disorder is treated with mood stabilizers and antipsychotics as maintenance therapy.

CLINICAL PRESENTATION

1. The essential feature of bipolar spectrum disorders is a history of mania or hypomania that is not caused by any other medical condition, substance, or psychiatric disorder (see Table 78–2 for secondary causes of mania).1,2 The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) of the American Psychiatric Association (APA) details the present understanding of mood disorders.1 Bipolar disorder is divided into four subtypes based on the identification of specific mood episodes: bipolar I, bipolar II, cyclothymic disorder, and bipolar disorder not otherwise specified. See Table 78–3 for a definition of mood

</table>

The length and severity of a mood episode and the interval between episodes varies from patient to patient. Manic episodes are usually briefer and end more abruptly than major depressive episodes. The average length of untreated manic episodes ranges from 4 to 13 months. Episodes can occur regularly (at the same time or season of the year) and often cluster at 12-month intervals. Women have more depressive episodes than manic episodes, whereas men have a more even distribution of episodes.

For bipolar I disorder, 90% of individuals who experience a manic episode later have multiple recurrent major depressive, manic, hypomanic, or mixed episodes alternating with a normal mood state.

Approximately 5%–15% of patients with bipolar II disorder will develop a manic episode over a 5-year period. If a manic or mixed episode develops in a patient with bipolar II disorder, the diagnosis is changed to bipolar I disorder.

Patients with cyclothymic disorder have a 15%–50% risk of later developing a bipolar I or II disorder. Data from American Psychiatric Association,1 American Psychiatric Association,1 and Goldberg and Harrow.1

Approximately 5%–15% of patients with bipolar II disorder will develop a manic episode over a 5-year period. If a manic or mixed episode develops in a patient with bipolar II disorder, the diagnosis is changed to bipolar I disorder. Data from American Psychiatric Association,1 American Psychiatric Association,1 and Goldberg and Harrow.1
disorders by type of episode. The mood states are further separated into four subcategories to differentiate the current or most recent mood episode: major depressive, manic, hypomanic, or mixed. See Table 78–4 for the evaluation and diagnostic criteria of mood episodes. A new concept of “bipolar spectrum disorder” has been suggested that broadens the diagnosis to include dysthymia, cyclothymia, drug-induced hypomania, and recurrent unipolar depression. Bipolar disorder is a cyclic mood disorder, and patients may sequentially experience different types of episodes with or without a period of normal mood ( euthymia) between. Persons with bipolar disorder can have mood fluctuations that continue for months, or after one episode they can sometimes go years without recurrence of any type of mood episode. Comorbid psychiatric disorders associated with bipolar disorder include but are not limited to the following: alcohol and substance abuse, personality disorders, and anxiety disorders such as panic disorder, social anxiety disorder, and obsessive-compulsive disorder.

### MAJOR DEPRESSIVE EPISODE

Bipolar depression is often underdiagnosed and is frequently misdiagnosed as major depressive disorder. Approximately 95% of patients with bipolar disorder experience episodes of depression during their lifetime. Compared with manic episodes, depressive episodes are more frequent, longer lasting, and occur more often in bipolar II than in bipolar I disorder. Over a person’s lifetime, depressive episodes can account for up to 80% of all mood episodes. Recurrent depressive episodes are more common in women compared to men. In bipolar depression, patients have an increased suicide risk and often have mood lability, hypomania, low energy, psychomotor retardation, cognitive impairment, anhedonia, decreased sexual activity, slowed speech, carbohydrate craving, and weight gain (also called atypical depressive features). Delusions, hallucinations, and suicide attempts are more common in bipolar depression than in unipolar depression.

### MANIC EPISODE

For a diagnosis of mania, the symptoms must last at least 1 week, the mood must be elevated (expansive or irritable), and there must be an impairment in functioning. Acute mania usually begins abruptly, and symptoms escalate over several days. Common symptoms of mania include grandiosity, decreased need for sleep or food, pressured speech, flight of ideas (racing thoughts), distractibility, increased activity, poor judgment, and involvement in pleasurable activities with potentially negative consequences. Patients with acute mania often have psychotic symptoms, thus some patients are incorrectly diagnosed as having schizophrenia. Mania symptoms that can resemble paranoid schizophrenia are bizarre behavior, hallucinations, and paranoid or grandiose delusions. Seasonal changes,
tumor, or dementia), medications, or substance use. Symptoms found in hypomanic episodes are similar to those of cocaine- or antidepressant-induced mood disorders; thus the differential diagnosis should rule out any substance-induced or medical conditions that present with elevated mood. Hypomanic states should be closely monitored, because 5% to 15% of patients can rapidly switch to a manic episode.

**MIXED EPISODE**

Bipolar “mixed episode” (previously known as mixed state, dysphoric mania, or depressive mania) is defined as the simultaneous occurrence of manic and depressive symptoms. Mixed mood states occur in up to 40% of all episodes and are more common in younger and older patients and in females. Mixed episodes are often difficult to diagnose and treat because of the fluctuating clinical presentation. Patients with mixed states often have comorbid alcohol and substance abuse, severe anxiety symptoms, a higher suicide rate, and a poorer prognosis.

**COURSE OF ILLNESS**

1. Bipolar disorder is frequently not recognized and treated for many years because of its fluctuating course and episodic mood states. The onset of bipolar disorder is rare before puberty, but its incidence increases during late adolescence and into early adulthood (usually between the ages of 15 and 30 years). The average age of onset of a first manic episode is 21 years for both men and women. Bipolar disorder affects an estimated 1% of children and adolescents and is often harder to recognize, diagnose, and treat than in a typical adult patient. Before the onset of mania, adolescents can exhibit irritability, hyperactivity, impulsivity, emotional lability, poor judgment, marked anxiety, insomnia, depression, and psychosis. The first episode in females is more likely to be a major depressive episode, whereas males are more likely to first experience a manic episode. Women are more likely to have mixed states, depressive episodes, and rapid cycling compared with men. Onset of manic episodes after the age of 60 years is rare and is likely caused by a medical or neurologic condition (e.g., stroke, tumor, or dementia), medications, or substance use.

2. The kindling theory is used to explain why bipolar disorder progresses over one’s life and why preventative treatment is imperative. Episodes can become longer in duration and more frequent with aging. Usually there is a period of normal functioning between episodes, but approximately 20% to 30% of patients with bipolar I disorder and 15% with bipolar II disorder have no period of euthymia because of mood lability, residual mood symptoms, or a direct switch to the opposite polarity.

Rapid cycling (more than four mood episodes per year) is more common in females and occurs in approximately 10% to 20% of bipolar I and II disorder patients. Frequent and severe episodes of depression appear to be the most common hallmark of rapid cycling. Use of alcohol, stimulants, antidepressants, sleep deprivation, hypothyroidism, and seasonal changes can play a role in rapid cycling. Seasonal patterns of mania in the summer and depression during the winter have been observed. Rapid-cycling patients have a poorer long-term prognosis and often require combination therapies.

Fluctuations in hormones and neurotransmitters during the luteal phase of the menstrual cycle, postpartum period, and during perimenopause (starting ~10 years before menopause) can precipitate mood changes and increase cycling. Women with bipolar I disorder are at greater risk for relapse into mania or depression during the postpartum period. If a severe mood episode occurs postpartum, there is an increased risk for recurrences during subsequent postpartum periods.

Alcohol and substance abuse is common among patients with bipolar disorder and can have a significant impact on the age of onset, course of the illness, and response to treatment. Alcohol and drug abuse or dependence has been reported in 46% and 41% of bipolar patients, respectively. Patients with substance use disorders are more likely to have an earlier onset of their illness, mixed states, higher rates of relapse, a poorer response to treatment, comorbid personality disorders, increased suicide risk, and more psychiatric hospitalizations. Bipolar patients often self-medicate with substances such as alcohol or cocaine during episodes, resulting in further impairment of judgment, poor impulse control, treatment nonadherence, and a worsening of the clinical course.

More than one-half (55%–65%) of bipolar I patients have some degree of functional disability after the onset of their illness, and approximately 10% to 20% of bipolar patients have severe impairment in their psychosocial and occupational functioning. In a 1-year longitudinal study in 258 bipolar patients, two-thirds had four or more mood episodes a year despite comprehensive pharmacologic treatment, and approximately 33.2% of the year was spent being depressed compared to 10.8% of the time in a manic phase. Compared with the general population, individuals with bipolar disorder have a 2.3-times higher mortality rate. Suicide attempts occur in up to 50% of patients with bipolar disorder, and approximately 10% to 19% of individuals with bipolar I disorder commit suicide. Studies suggest patients with bipolar II disorder have more suicide attempts than bipolar I patients. Suicidal ideation and attempts are most likely to occur in a depressive or mixed state and in patients with personality disorders, psychotic features, and/or a comorbid alcohol- and substance-use disorder. Acutely manic or depressed patients can need hospitalization because they are suicidal, have violent or aggressive behavior, or lack appropriate judgment and insight. Accidental deaths are more frequent during manic episodes when the person has grandiosity, hallucinations, or delusions that result in risk-taking behaviors. In addition, bipolar patients have a higher mortality from endocrine, respiratory, and cardiovascular disease that can be related to higher rates of obesity, smoking, alcohol and substance abuse, infections, and lack of medical care.

The best predictor for level of functioning during a person’s lifetime is adherence with medication treatment. Medication discontinuation occurs in up to 50% of patients secondary to intolerance of drug-induced side effects. Failure to recognize the disorder, reluctance to acknowledge it, or poor adherence with treatment are reasons an estimated two-thirds of patients with bipolar disorder do not receive appropriate treatment. Nonadherence with pharmacologic treatment and substance abuse are major factors in relapse and hospitalizations.

**TREATMENT**

**TREATMENT DESIRED OUTCOME**

The desired outcome for bipolar disorder is to prevent an acute manic, hypomanic, or depressive episode, to maintain good functioning, and to prevent further episodes of mania or depression.
The general principles and goals for the management of bipolar disorder are found in Table 78–5.

**GENERAL APPROACH TO TREATMENT**

1. Treatment of bipolar disorder must be individualized because the clinical presentation, severity, and frequency of episodes vary widely among patients. Treatment approaches should include both nonpharmacologic and pharmacologic strategies. Patients and family members should be educated about bipolar disorder (e.g., symptoms, causes, and course) and treatment options. Long-term adherence to treatment is the most important factor in achieving stabilization of the disorder.

2. The treatment of bipolar disorder can vary depending on what type of episode the patient is experiencing. Once diagnosed with bipolar disorder, patients should remain on a mood stabilizer (e.g., lithium, valproate) for their lifetime. During acute episodes, medications can be added and then tapered once the patient is stabilized and euthymic. For example, when treating a patient for mania with psychotic features, the patient should be on a mood stabilizer and an antipsychotic. If the antipsychotic is the patient’s maintenance therapy, the dose should be increased or perhaps the medication should be changed altogether if the patient goes into a manic episode. If treating a patient for a severe depressive episode, a clinician may need to maximize the dose of the mood stabilizer or add another medication (e.g., quetiapine).

**Nonpharmacologic Therapy**

The basics of nonpharmacologic approaches should address issues of adequate nutrition, sleep, exercise, and stress reduction. Sleep deprivation, high stress, and deficiencies in dietary essential amino acids, fatty acids, vitamins, and minerals can exacerbate mood episodes and result in poorer outcomes. Mood charting is an effective strategy in detecting early signs and symptoms of mania and depression. Another effective treatment is to combine medications with adjunctive psychoeducational programs, supportive counseling, insight-oriented psychotherapy (individual or group), couples or family therapy, cognitive behavioral therapy, and communication enhancement training. Most communities have self-help, support groups, and mental health organizations that provide information, educational materials, and counseling. For public information, individuals can contact the Depression and Bipolar Support Alliance at 800–826-3632 and www.dbsalliance.org; the National Alliance on Mental Illness (NAMI) at 800–950–6264 (help line) and www.nami.org; Mental Health America (National Mental Health Association) 800–969–6642 (resource center) and www.mh.org; and the National Institute of Mental Health at 866–615–6464 and www.nimh.nih.gov.

Several nonpharmacologic treatment strategies (e.g., electroconvulsive therapy [ECT], high-intensity bright light therapy, phase-advanced sleep schedule, and partial or complete sleep deprivation) have been used in the treatment of bipolar disorder. The use of ECT for the treatment of severe episodes of mania, depression, psychotic features (e.g., hallucinations or delusions), mixed episodes, or rapid cycling should be considered for those patients who do not respond to medications. Repetitive transcranial magnetic stimulation (rTMS) has been reported to be effective in bipolar disorder. Most data include the use of rTMS as augmentation in drug-resistant bipolar depression. A small amount of data support the use of rTMS in treating mania and for maintenance treatment in bipolar depression. Vagus nerve stimulation (VNS) may also have a role in treatment-resistant rapid-cycling bipolar disorder. More studies are needed to assess the role of VNS in bipolar disorder.

**Pharmacologic Therapy**

Pharmacotherapy is crucial for the acute and maintenance treatment of bipolar disorder and includes lithium, valproate, carbamazepine, lamotrigine, first- and second-generation antipsychotics, and adjunctive agents such as antidepressants and benzodiazepines. General treatment guidelines for the acute treatment of mood episodes in patients with bipolar I disorder are found in Table 78–6.

Product information, dosing and administration, and clinical use for agents used in the treatment of bipolar disorder are found in Table 78–7. The term mood stabilizer is often used to describe the class of medications used in the treatment of bipolar disorder, but this may not be accurate as some medications are more effective for acute mania, some for the depressive episode, and others for the maintenance phase. Lithium, valproate (or divalproex sodium), extended-release carbamazepine, aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of acute mania in bipolar disorder; only lithium, divalproex sodium, aripiprazole, olanzapine, and lamotrigine are approved for the maintenance treatment of bipolar disorder. Quetiapine is the only monotherapy antipsychotic that is FDA approved for bipolar depression. Lithium is the drug of choice for bipolar disorder with euphoric mania, whereas valproate has better efficacy for mixed states, irritable/dysphoric mania, and rapid cycling compared with lithium.

Combination therapies (e.g., lithium plus valproate or carbamazepine; lithium or valproate plus SGA) can provide better acute response and long-term prevention of relapse and recurrence than monotherapy in some bipolar patients, particularly those with mixed states or rapid cycling. The majority of patients hospitalized for an acute episode will be on combination therapy.

</table>

- ECT, electroconvulsive therapy; MAOI, monoamine oxidase inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SGA, second-generation antipsychotic, SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.
- Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.
- Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy of bipolar I disorder. Lamotrigine may be initiated during acute treatment with plans to transition to this medication for long-term maintenance. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (i.e., lamotrigine doses must be halved from standard dosing titration).
- Controversy exists concerning the use of antidepressants, and they are often considered third line in treating acute bipolar depression, except in patients with no recent history of severe acute mania or potentially in bipolar II patients.
- ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

Data from American Psychiatric Association; CANMAT & ISBD; and Suppes et al.

Several guidelines and algorithms have been published regarding the treatment of bipolar disorder, and these are generally based on the best available data and the clinical consensus of experts. The Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders (ISBD) published updated treatment guidelines in 2009. A new edition of Practice Guideline for the Treatment of Patients with Bipolar Disorder published by the APA is expected to be released in the near future. The APA guidelines address the diagnosis, clinical course, epidemiology, and treatment strategies for adults but are not intended to be used as a standard of psychiatric care. The Texas Department of Mental Health and Mental Retardation has developed and implemented algorithms in the public mental health system to improve treatment outcomes with bipolar I disorder. Several other states have also adopted and implemented programs similar to the Texas algorithm project. The Texas algorithm project data are in the process of being updated. The last updates posted are from 2007. In addition, an international task force of the World Federation of Societies of Biological Psychiatry (WFSBP) has published guidelines for the treatment of bipolar depression and mania. The WFSBP mania guidelines were updated in 2009, but bipolar depression (2002) and maintenance (2003) guidelines have yet to be updated.

Based on the CANMAT and ISBD guidelines and available research, an example treatment algorithm and guidelines for acute mood episodes in adult patients with bipolar I disorder are listed in Table 78–6. Because newer anticonvulsants, SGAs, and combination therapies are under investigation for bipolar disorder, published guidelines, algorithms, and decision trees can quickly become out of date as new scientific knowledge evolves. Selection of treatments for acute mood episodes (e.g., manic or mixed, depressive, or rapid cycling) and for maintenance strategies to prevent relapses of mood episodes should be individualized. Treatment plans should be based on patient-specific characteristics, comorbid psychiatric and medical conditions, and avoidance of drug interactions and adverse effects.

There are few controlled studies in children and adolescents with bipolar disorder, thus little is known about the long-term efficacy and safety of specific agents or for combination therapies in this population. Lithium, valproic acid, and carbamazepine are all used in pediatric bipolar disorder. Lithium is the only medication...

Data from American Psychiatric Association; Goldberg and Harrow; Goodnick; Manji et al.; White; and CANMAT & ISBD. FDA approved agents may be used as monotherapy in various phases of the illness as noted by. FDA approved for acute mania. FDA approved for acute bipolar depression. FDA approved for maintenance.
CHAPTER 78

Bipolar Disorder

Lithium was first used in 1949 as a treatment for mania and was approved in 1972 in the United States for the treatment of acute mania and for maintenance therapy. Despite numerous investigations into the biologic and clinical properties of lithium, there is no unified theory for its mechanism of action. Chronic lithium administration may modulate gene expression and have neuroprotective effects. Lithium has unique pharmacokinetics because it is a monovalent cation. Lithium is rapidly absorbed, is widely distributed with no protein binding, is not metabolized, and is excreted unchanged in the urine and in other body fluids. Lithium requires regular assessment of renal and thyroid functioning and lithium blood level monitoring to minimize adverse effects. Lithium is frequently combined with either FGAs or SGAs for treatment of euphoric acute mania with psychotic features. Concomitant use of lithium with valproate or carbamazepine appears to be well tolerated but can increase the risk of sedation, weight gain, gastrointestinal complaints, and tremor.

Lithium is frequently combined with either FGAs or SGAs for treatment of euphoric acute mania with psychotic features. Case reports of neurotoxicity (e.g., delirium, cerebellar dysfunction, extrapyramidal symptoms, and severe tremors) have been published in elderly patients receiving lithium and FGAs. Combining lithium with calcium channel blockers is not recommended because of reports of neurotoxicity and severe bradycardia with verapamil or diltiazem. Acute neurotoxicity and delirium have been reported in patients receiving ECT with lithium (even at reduced dosages); therefore, lithium should be withdrawn and discontinued at least 2 days before ECT and should not be resumed until 2 to 3 days after the last treatment.

Adverse Effects

Approximately 35% to 93% of patients treated with lithium will experience adverse effects. These are divided into those that occur early in therapy and are generally innocuous and transient, those that occur with long-term therapy and are usually not dose related, and toxic effects that occur with high serum concentrations.

Initial side effects are often dose related and are worse at peak serum concentrations (1–2 hours postdose). Standard approaches for minimizing adverse effects include lowering the dose, taking smaller doses with food, using extended-release products, and trying once-daily dosing at bedtime. Gastrointestinal distress (e.g., nausea, vomiting, dyspepsia, and diarrhea) can be minimized by the standard approaches or by adding antacids or antidiarrheal agents. Diarrhea can sometimes be managed by switching from tablet or capsule formulation to liquid formulation. Diarrhea produced by lithium is commonly an osmotic diarrhea, and therefore switching to a formulation that clears the gut quickly can ameliorate symptoms. Muscle weakness and lethargy develop in about 30% of patients, but these symptoms are usually transient. Polydipsia with polyuria and nocturia occurs in up to 70% of patients and can be managed by changing to once-daily bedtime dosing.

As many as 40% of patients complain of headache, memory impairment, confusion, poor concentration, and impaired motor performance. A fine hand tremor can be evident in up to 50% of patients. Stress, concomitant use of antidepressants or antipsychotics, caffeine, sympathomimetics, and impending toxicity can exacerbate the tremor. Strategies to reduce the tremor include standard approaches (e.g., switch to long-acting preparation, lower dose if possible) or adding a β-adrenergic antagonist (e.g., propranolol 20–120 mg/day).

Lithium reduces the kidney’s ability to concentrate urine and can cause a nephrogenic diabetes insipidus characterized by low urine specific gravity and a low osmolality polyuria (urine volumes greater than 3 L/day). Lithium-induced nephrogenic diabetes insipidus is treated with loop diuretics, thiazide diuretics, or triamterene. If a thiazide diuretic is used (e.g., hydrochlorothiazide 50 mg/day), lithium doses should be decreased by 50%, and potassium levels should be monitored. Amiloride, a potassium-sparing diuretic, has weaker natriuretic effects than thiazides and appears to be relatively safe with minimal effect on lithium clearance. Potassium supplements have been suggested as another treatment for lithium-induced polyuria. Fluid restriction is not recommended because dehydration increases the risk of lithium toxicity. If edema occurs, treatment approaches include lowering sodium intake or using a diuretic (e.g., spironolactone); close monitoring for lithium toxicity is necessary because these treatments often increase lithium concentrations.

Patients on long-term lithium therapy have a 10% to 20% risk of developing morphologic renal changes (e.g., glomerular sclerosis,
tubular atrophy, and interstitial nephritis) that is associated with impairment of water resorption and increased serum creatinine concentrations. Lithium rarely causes nephrotoxicity if patients are maintained on the lowest effective dose, if adequate hydration is maintained, and if toxicity is avoided. Lithium should be avoided in patients with preexisting renal disease unless there is frequent monitoring.

Lithium is concentrated in the thyroid gland, interferes with thyroid hormone synthesis, and can induce the formation of thyroid antibodies. Up to 30% of patients on maintenance lithium therapy develop transiently elevated thyroid-stimulating hormone concentrations, and 5% to 35% of patients develop a goiter and/or hypothyroidism. Lithium-induced hypothyroidism is not dose-related, is observed 10 times more frequently in women (particularly in those with rapid cycling), and usually occurs after 6 to 18 months of therapy. Hypothyroidism does not require discontinuation of lithium, because exogenous thyroid hormone (i.e., levothyroxine) can be added to the regimen. When lithium is discontinued, the need for exogenous thyroid hormone should be reassessed, because hypothyroidism can be reversible.

Lithium can cause a variety of benign and reversible cardiac effects, particularly T-wave flattening or inversion (in up to 30% of patients), atrioventricular block, and bradycardia. Lithium rarely causes myocarditis, sinus node dysfunction, or sinoatrial block but can aggravate ventricular arrhythmias and atrial premature contractions. If a patient has significant preexisting cardiac disease, consultation with a cardiologist and an electrocardiogram is recommended at baseline and during lithium therapy.

Other late-appearing lithium side effects include benign reversible leukocytosis and a variety of dermatologic effects (e.g., acne and acneiform eruptions, alopecia, exacerbation of psoriasis, pruritic dermatitis, maculopapular rashes, and folliculitis). Weight gain is common (~20% of patients gain >10 kg [22 lb]) and can be related to fluid retention, the consumption of high-calorie beverages as a result of polydipsia, or to a decreased metabolic rate because of hypothyroidism. Decreased libido, sexual dysfunction, dry mouth, alterations in taste, changes in glucose tolerance, hypercalcaemia, and hyperparathyroidism have been reported. Severe neurologic disturbances such as coarse hand tremors, ataxia, slurred speech, myasthenia gravis, extrapyramidal syndrome, pseudotumor cerebri, and papilledema are occasionally observed.

Lithium is an extremely toxic drug if accidentally or intentionally taken in overdose. Lithium toxicity can occur with blood levels greater than 1.5 mEq/L (mmol/L), but elderly patients can have symptoms of toxicity at therapeutic levels. Severe lithium intoxication occurs when concentrations are higher than 2.0 mEq/L (mmol/L), and there is a worsening in several key symptoms: gastrointestinal (e.g., vomiting, diarrhea, or incontinence); coordination (e.g., severe fine to coarse hand tremor, unstable gait, slurred speech, and muscle twitching); and cognition (e.g., poor concentration, drowsiness, disorientation, apathy, and coma). Several reports of seizures, cardiac dysrhythmia, permanent neurologic impairments with ataxia and deficits in memory, and kidney damage with reduced glomerular filtration rate have been reported after lithium intoxication.
